The most prominent physiologic effect of general anesthesia induction is a decrease in systemic arterial blood pressure. The causes include direct vasodilation, myocardial depression, or both; a blunting of baroreceptor control; and a generalized decrease in central sympathetic tone. Agents vary in the magnitude of their specific effects, but in all cases the hypotensive response is enhanced by underlying volume depletion or preexisting myocardial dysfunction.

**Respiratory Effects of General Anesthesia**

Nearly all general anesthetics reduce or eliminate both ventilatory drive and the reflexes that maintain airway patency. Therefore, ventilation generally must be assisted or controlled for at least some period during surgery. The gag reflex is lost, and the stimulus to cough is blunted. Lower esophageal sphincter tone also is reduced, so both passive and active regurgitation may occur. Endotracheal intubation has been a major reason for a decline in the number of aspiration deaths during general anesthesia. Muscle relaxation is valuable during the induction of general anesthesia where it facilitates management of the airway, including endotracheal intubation. Neuromuscular blocking agents commonly are used to effect such relaxation (see Chapter 11). Alternatives to an endotracheal tube include a face mask and a laryngeal mask, an inflatable mask placed in the oropharynx forming a seal around the glottis. Airway management techniques are based on the anesthetic procedure, the need for neuromuscular relaxation, and the physical characteristics of the patient.

**Hypothermia**

Patients commonly develop hypothermia (body temperature < 36°C) during surgery. The reasons include low ambient temperature, exposed body cavities, cold intravenous fluids, altered thermoregulatory control, and reduced metabolic rate. Metabolic rate and total body O₂ consumption decrease with general anesthesia by about 30%, reducing heat generation. Hypothermia may lead to an increase in perioperative morbidity. Prevention of hypothermia is a major goal of anesthetic care.

**Nausea and Vomiting**

Nausea and vomiting continue to be significant problems following general anesthesia and are caused by an action of anesthetics on the chemoreceptor trigger zone and the brainstem vomiting center, which are modulated by 5HT, histamine, ACh, DA, and NK1. The 5HT₃ receptor antagonists ondansetron, dolasetron, and palonosetron (see Chapters 13 and 50) are

Effective in suppressing nausea and vomiting. Common preventive strategies include anesthetic induction with propofol; the combined use of droperidol, metoclopramide, and dexamethasone; and avoidance of nitrous oxide (N_2O). A new subclass of antiemetic drugs includes NK_1 antagonists (e.g., aprepitant, rolapitant).

Other Emergent and Postoperative Phenomena

Hypertension and tachycardia are common during emergence from anesthesia as the sympathetic nervous system regains its tone and is enhanced by pain. Myocardial ischemia can appear or worsen during emergence in patients with coronary artery disease. Emergence excitement occurs in 5%–30% of patients and is characterized by tachycardia, restlessness, crying, moaning, and thrashing. Neurologic signs, including delirium, spasticity, hyperreflexia, and Babinski sign, are often manifest in the patient emerging from anesthesia. Postanesthesia shivering occurs frequently because of core hypothermia. A small dose of meperidine (12.5 mg) lowers the shivering trigger temperature and effectively stops the activity. The incidence of all of these emergence phenomena is greatly reduced with opioids and α_2 adrenergic receptor agonists (dexmedetomidine).

Airway obstruction may occur during the postoperative period because of residual anesthetic effects. Pulmonary function is reduced following all types of anesthesia and surgery, and hypoxemia may occur. In the immediate postoperative period, pulmonary function reduction can be compounded by the respiratory suppression associated with opioids used for pain control. Regional anesthetic techniques are an important part of a perioperative approach that employs local anesthetic wound infiltration; epidural, spinal, and plexus blocks; and nonsteroidal anti-inflammatory drugs, opioids, α_2 adrenergic receptor agonists, and NMDA receptor antagonists.

Actions and Mechanisms of General Anesthetics

The Anesthetic State

The components of the anesthetic state include

- Amnesia
- Analgesia
- Unconsciousness
- Immobility in response to noxious stimulation
- Attenuation of autonomic responses to noxious stimulation

The potency of general anesthetic agents is measured by determining the concentration of general anesthetic that prevents movement in response to surgical stimulation. For inhalational anesthetics, anesthetic potency is measured in MAC units, with 1 MAC defined as the minimum alveolar concentration that prevents movement in response to surgical stimulation in 50% of subjects. The strengths of MAC as a measurement are the following:

- Alveolar concentrations can be monitored continuously by measuring end-tidal anesthetic concentration using infrared spectroscopy or mass spectrometry.
- MAC provides a direct correlate of the free concentration of the anesthetic at its site of action in the CNS.
- MAC is a simple-to-measure end point that reflects an important clinical goal.

End points other than immobilization also can be used to measure anesthetic potency. For example, the ability to respond to verbal commands (MAC_V) and the ability to form memories also have been correlated with alveolar anesthetic concentration. Verbal response and memory formation are suppressed at a fraction of MAC. The ratio of the anesthetic concentrations required to produce amnesia and immobility vary significantly among different inhalational anesthetic agents.

Generally, the potency of intravenous agents is defined as the free plasma concentration (at equilibrium) that produces loss of response to surgical incision (or other end points) in 50% of subjects.

Mechanisms of Anesthesia

The molecular and cellular mechanisms by which general anesthetics produce their effects have remained one of the great mysteries of pharmacology. The leading unitary theory was that anesthesia is produced by perturbation of the physical properties of cell membranes. This thinking was based largely on the observation that the anesthetic potency of a gas correlated with its solubility in olive oil. This correlation is referred to as the Meyer-Overton rule. Clear exceptions to the Meyer-Overton rule (Franks, 2006) suggest protein targets that may account for anesthetic action.

Increasing evidence supports the hypothesis that different anesthetic agents produce specific components of anesthesia by actions at different molecular targets. Given these insights, the unitary theory of anesthesia has been largely discarded.

Molecular Mechanisms of General Anesthetics

Most intravenous general anesthetics act predominantly through GABA_A receptors and perhaps through some interactions with other ligand-gated ion channels such as NMDA receptors and two-pore K+ channels.
Chloride channels gated by the inhibitory GABA<sub>A</sub> receptors (see Figures 14–5 and 14–11) are sensitive to a wide variety of anesthetics, including the halogenated inhalational agents, many intravenous agents (propofol, barbiturates, and etomidate), and neurosteroids. At clinical concentrations, general anesthetics increase the sensitivity of the GABA<sub>A</sub> receptor to GABA, thereby enhancing inhibitory neurotransmission and depressing nervous system activity. The action of anesthetics on the GABA<sub>A</sub> receptor probably is mediated by binding of the anesthetics to specific sites on the GABA<sub>A</sub> receptor protein (but they do not compete with GABA for its binding site). The capacity of propofol and etomidate to inhibit the response to noxious stimuli is mediated by a specific site on the β<sub>3</sub> subunit of the GABA<sub>A</sub> receptor, whereas the sedative effects of these anesthetics are mediated by the β<sub>1</sub> subunit.

Structurally related to the GABA<sub>A</sub> receptors are other ligand-gated ion channels, including glycine receptors and neuronal nicotinic ACh receptors (see Figure 14–5). Glycine-gated Cl<sup>−</sup> channels (glycine receptors) may play a role in mediating inhibition by anesthetics of responses to noxious stimuli. Inhalational anesthetics enhance the capacity of glycine to activate glycine receptors, which play an important role in inhibitory neurotransmission in the spinal cord and brainstem. Propofol, barbiturates, and barbiturates also potentiate glycine-activated currents, whereas etomidate and ketamine do not. Subanesthetic concentrations of the inhalational anesthetics inhibit some classes of neuronal nicotinic ACh receptors, which seem to mediate other components of anesthesia such as analgesia or amnesia.

Ketamine, nitrous oxide, cyclopropane, and xenon are the only general anesthetics that do not have significant effects on GABA<sub>A</sub> or glycine receptors. These agents inhibit a different type of ligand-gated ion channel, the NMDA receptor (see Figure 14–12 and Table 14–2). NMDA receptors are glutamate-gated cation channels that are selectively for Ca<sup>2+</sup> and are involved in long-term modulation of synaptic responses (long-term potentiation) and glutamate-mediated neurotoxicity.

Halogenated inhalational anesthetics activate some members of a class of K<sup>+</sup> channels known as two-pore domain channels; other two-pore domain family members are activated by xenon, N<sub>2</sub>O, and cyclopropane. These channels are located in both presynaptic and postsynaptic sites. The postsynaptic channels may be the molecular locus through which these agents hyperpolarize neurons.

### Cellular Mechanisms of Anesthesia

General anesthetics produce two important physiologic effects at the cellular level:

1. Inhalational anesthetics can hyperpolarize neurons. Neuronal hyperpolarization may affect pacemaker activity and pattern-generating circuits.
2. Both inhalational and intravenous anesthetics have substantial effects on synaptic transmission and much smaller effects on action potential generation or propagation.

Inhalational anesthetics inhibit excitatory synapses and enhance inhibitory synapses in various preparations. The inhalational anesthetics inhibit neurotransmitter release. Inhalational anesthetics also can act postsynaptically, altering the response to released neurotransmitter. These actions are thought to be due to specific interactions of anesthetic agents with neurotransmitter receptors.

Intravenous anesthetics produce a narrower range of physiological effects. Their predominant actions are at the synapse, where they have profound and relatively specific effects on the postsynaptic response to released neurotransmitter. Most of the intravenous agents act predominantly by enhancing inhibitory neurotransmission, whereas ketamine predominantly inhibits excitatory neurotransmission at glutamatergic synapses.

### Anatomic Sites of Anesthetic Action

In principle, general anesthetics could interrupt nervous system function at myriad levels, including peripheral sensory neurons, the spinal cord, the brainstem, and the cerebral cortex. Most anesthetics cause, with some exceptions, a global reduction in CMB and in CBF. A consistent feature of general anesthesia is a suppression of metabolism in the thalamus (Alkire et al., 2008), which serves as a major relay by which sensory input from the periphery ascends to the cortex. Suppression of thalamic activity may serve as a switch between the awake and anesthetized states (Franks, 2008). General anesthesia also suppresses activity in specific regions of the cortex, including the mesial parietal cortex, posterior cingulate cortex, precuneus, and inferior parietal cortex.

Simultaneously, natural sleep and the anesthetized state suggest that anesthetics might also modulate endogenous sleep-regulating pathways, which include VLPO and tuberomammillary nuclei. VLPO projects inhibitory GABAergic fibers to ascending arousal nuclei, which in turn project to the cortex, forebrain, and subcortical areas; release histamine, 5HT, orexin, NE, and ACh; and mediate wakefulness. Intravenous and inhalational agents with activity at GABA<sub>A</sub> receptors can increase the inhibitory effects of VLPO, thereby suppressing consciousness. Dexamethasone, an α<sub>1</sub> adrenergic agonist, also increases VLPO-mediated inhibition by suppressing the inhibitory effect of locus ceruleus neurons on VLPO. Finally, both intravenous and inhalational anesthetics depress hippocampal neurotransmission, a probable locus for their amnestic effects.

### Parenteral Anesthetics

Parenteral anesthetics are the most common drugs used for anesthetic induction of adults. Their lipophilicity, coupled with the relatively high perfusion of the brain and spinal cord, results in rapid onset and short duration after a single bolus dose. These drugs ultimately accumulate in fatty tissue. Each of these anesthetics has its own unique properties and side effects (Tables 21–1 and 21–2). Propofol is advantageous for procedures where rapid return to a preoperative mental status is desirable. Etomidate usually is reserved for patients at risk for hypotension or myocardial ischemia. Ketamine is best suited for patients with asthma or for children undergoing short, painful procedures. Thiopental has a long-established track record of safety; however, clinical use is limited currently by availability.

### Pharmacokinetic Principles

Parenteral anesthetics are small, hydrophobic, substituted aromatic or heterocyclic compounds (Figure 21–1). Hydrophobicity is the key factor governing their pharmacokinetics. After a single intravenous bolus, these drugs preferentially partition into the highly perfused and lipophilic tissues of the brain and spinal cord, where they produce anesthesia within a single circulation time. Subsequently, blood levels fall rapidly, resulting in drug redistribution out of the CNS back into the blood. The anesthetic then diffuses into less-perfused tissues, such as muscle and viscera, and at a slower rate into the poorly perfused but very hydrophobic adipose tissue. Termination of anesthesia after single boluses of parenteral anesthetics primarily reflects redistribution out of the CNS rather than metabolism (see Figure 2–4).

After redistribution, anesthetic blood levels fall according to a complex interaction between the metabolic rate and the amount and lipophilicity of the drug stored in the peripheral compartments. Thus, parenteral anesthetic half-lives are “context sensitive,” and the degree to which a given anesthetic half-life is contextually varies greatly from drug to drug, as might be predicted based on their differing hydrophobicities and metabolic clearances (Figure 21–2; Table 21–1). For example, after a single bolus of thiopental, patients usually emerge from anesthesia within 10 min; however, a patient may require more than a day to awaken from a prolonged thiopental infusion. Most individual variability in sensitivity to parenteral anesthetics can be accounted for by pharmacokinetic factors. For example, in patients with lower cardiac output, the relative perfusion of the brain and the fraction of anesthetic dose delivered to the brain are higher; thus, patients in septic shock or with cardiomyopathy usually require lower doses of parenteral anesthetics. The elderly also typically require a smaller parenteral anesthetic dose, primarily because of a smaller initial volume of distribution.
Specific Parenteral Agents

**Propofol, Fospropofol**

Propofol is the most commonly used parenteral anesthetic in the U.S. Fospropofol is a prodrug form that is converted to propofol in vivo. The clinical pharmacological properties of propofol are summarized in Table 21–1.

The active ingredient in propofol, 2,6-diisopropylphenol, is an oil at room temperature and insoluble in aqueous solutions. Propofol is formulated for intravenous administration as a 1% (10-mg/mL) emulsion in 10% soybean oil, 2.25% glycerol, and 1.2% purified egg phosphatide. In the U.S., disodium EDTA (0.05 mg/mL) or sodium metabisulfite (0.25 mg/mL) is added to inhibit bacterial growth. Propofol should be administered within 4 h of its removal from sterile packaging; unused drug should be discarded. The lipid emulsion formulation of propofol is associated with significant pain on injection and hyperlipidemia.

A new aqueous formulation of propofol, fospropofol, which is not associated with these adverse effects, is available for use for sedation in patients undergoing diagnostic procedures (Fechner et al., 2008). Fospropofol, which itself is inactive, is a phosphate ester prodrug of propofol that is hydrolyzed by endothelial alkaline phosphatases to yield propofol, phosphate, and formaldehyde. The formaldehyde is rapidly converted to formic acid, which then is metabolized by tetrahydrofolate dehydrogenase to CO2 and water.

**Clinical Use and ADME.** The induction dose of propofol in a healthy adult is 2–2.5 mg/kg. Dosages should be reduced in the elderly and in the presence of other sedatives and increased in young children. Because of its reasonably short elimination half-life, propofol often is used for maintenance of anesthesia as well as for induction. For short procedures, small boluses (10%–50% of the induction dose) every 5 min or as needed are effective. An infusion of propofol produces a more stable level (100–300 μg/kg/min) and is better suited for longer-term anesthetic maintenance. Sedating doses of propofol are 20–50% of those required for general anesthesia.

Propofol has a context-sensitive half-time of about 10 min with an infusion lasting 3 h and about 30 min for infusions lasting up to 8 h (see Figure 21–2). Propofol’s shorter duration of action after infusion can be explained by its very high clearance, coupled with the slow diffusion of drug from the peripheral to the central compartment. Propofol is metabolized in the liver by conjugation to sulfate and glucuronide to less-active metabolites that are renally excreted. Propofol is highly protein bound, and its pharmacokinetics, like those of the barbiturates, may be affected by conditions that alter serum protein levels. Clearance of propofol is reduced in the elderly. In neonates, propofol clearance is also reduced. By contrast, in young children, a more rapid clearance in combination with a larger central volume may necessitate larger doses of propofol for induction and maintenance of anesthesia.

Fospropofol produces dose-dependent sedation and can be administered in otherwise-healthy individuals at 2–8 mg/kg intravenously (delivered either as a bolus or by a short infusion over 5–10 min). The optimum dose for sedation is about 6.5 mg/kg. This results in a loss of consciousness in about 10 min. The duration of the sedative effect is approximately 45 min.

**Side Effects**

**Nervous System.** The sedation and hypnotic actions of propofol are mediated by its action on GABA_A receptors; agonism at these receptors results in an increased Cl−-conduction and hyperpolarization of neurons. Propofol suppresses the EEG, and, in sufficient doses, can produce burst suppression of the EEG. Propofol decreases the CMRO2, CBF, and intracranial and intraocular pressures by about the same amount as thiopental. Propofol has been used in patients at risk for cerebral ischemia; however, no human outcome studies have been performed to determine its efficacy as a neuroprotectant.

**Cardiovascular System.** Propofol produces a dose-dependent decrease in blood pressure that is significantly greater than that produced by thiopental. The fall in blood pressure can be explained by both vasoconstriction and possibly mild depression of myocardial contractility. Propofol appears to blunt the baroreceptor reflex and reduce sympathetic nerve activity. Propofol should be used with caution in patients at risk for, or intolerant of, decreases in blood pressure.

**Respiratory System.** Propofol produces a slightly greater degree of respiratory depression than thiopental. Patients given propofol should be monitored to ensure adequate oxygenation and ventilation. Propofol appears to be less likely than barbiturates to provoke bronchospasm and may be the induction agent of choice in patients with asthma. The bronchodilator properties of propofol may be attenuated by the metabisulfite preservative in some propofol formulations.

**Other Side Effects.** Propofol has a significant antiemetic action. Propofol elicits pain on injection that can be reduced with lidocaine and the use of larger arm and antecubital veins. A rare but potentially fatal complication, **PRIS**, has been described primarily in prolonged, higher-dose

---

*Typical effects of a single induction dose in humans, see text for references. Qualitative scale from – – – to +++ signifies slight, moderate, or large decrease or increase, respectively; 0 indicates no significant change.
infusions of propofol in young or head-injured patients (Kam and Card- 
done, 2007). PRIS is characterized by metabolic acidosis, hyperlipidemia, 
rhabdomyolysis, and liver enlargement.

**Etomidate**

Etomidate is a substituted imidazole that is supplied as the active d-isomer. 
Etomidate is poorly soluble in water and is formulated as a 2-mg/mL 
solution in 35% propylene glycol. Unlike thiopental, etomidate does not 
induce precipitation of neuromuscular blockers or other drugs frequently 
given during anesthetic induction.

**Clinical Use and ADME.** Etomidate is primarily used for anesthetic 
induction of patients at risk for hypotension. Induction doses of etomidate 
(see Table 21–1) are accompanied by a high incidence of pain on injec-
tion and myoclonic movements. Lidocaine effectively reduces the pain of 
injection, while myoclonic movements can be reduced by pretreatment 
with either benzodiazepines or opiates. Etomidate is pharmaco-
kinetically suitable for off-label infusion for anesthetic maintenance (10 μg/kg/min) or sedation (5 μg/kg/min); however, long-term infusions are not recom-
mented because of side effects.

An induction dose of etomidate has a rapid onset; redistribution lim-
its the duration of action. Metabolism occurs in the liver, primarily 
to inactive compounds. Elimination is both renal (78%) and biliary (22%). 
Compared to thiopental, the duration of action of etomidate increases less 
with repeated doses (see Figure 21–2).

**Side Effects**

**Nervous System.** Etomidate produces hypnosis and has no analgesic 
effects. The effects of etomidate on CBF, metabolism, and intracranial 
and intraocular pressures are similar to those of thiopental (without dropping 
mean arterial blood pressure). Etomidate produces increased EEG activity 
in epileptogenic foci and has been associated with seizures.

**Cardiovascular System.** Cardiovascular stability after induction is a major 
advantage of etomidate over either propofol or barbiturates. Induc-
tion doses of etomidate typically produce a small increase in heart rate 
and little or no decrease in blood pressure or cardiac output. Etomidate 
has little effect on coronary perfusion pressure while reducing myocardial 
O2 consumption.

**Respiratory and Other Side Effects.** The degree of respiratory depres-
sion due to etomidate appears to be less than that due to thiopental. Like 
methohexital, etomidate may induce hiccups; it does not significantly 
stimulate histamine release. Etomidate has been associated with nau-
sea and vomiting. The drug also inhibits adrenal biosynthetic enzymes 
required for the production of cortisol and some other steroids. Although 
the hemodynamic profile of etomidate may be advantageous, potent 
negative effects on steroid synthesis raise concerns about its use in 
trauma and critically ill patients (van den Heuvel et al., 2013) and obviate 
etomidate use for long-term infusion. A rapidly metabolized and ultra-
short-acting analogue, methoxycarbonyl-etomidate, retains the favorable 
pharmacological properties of etomidate but does not produce adrenocor-
tal suppression after bolus dosing (Cotton and Claing, 2009).

**Ketamine**

Ketamine is an arylcyclohexylamine and congener of phencyclidine. Ket-
amine is supplied as a mixture of the R+ and S- isomers even though 
the S-isomers is more potent and has fewer side effects. Although more 
lipophilic than thiopental, ketamine is water soluble.

**Clinical Use and ADME.** Ketamine is useful for anesthetizing patients 
at risk for hypotension and bronchospasm and for certain pediatric proce-
dures. However, significant side effects limit its routine use. Ketamine rapid-
ly produces a hypnotic state quite distinct from that of other anesthetics. 
Patients have profound analgesia, unresponsiveness to commands, and 
amnesia but may have their eyes open, move their limbs involuntarily, and 
breathe spontaneously. This cataleptic state has been termed dissociative 
anesthesia. The administration of ketamine has been shown to reduce the 
development of tolerance to long-term opioid use. Ketamine typically is 
administered intravenously but also is effective by intramuscular, oral, and 
rectal routes. Ketamine does not elicit pain on injection or true excitatory 
behavior as described for methohexital, although involuntary movements 
produced by ketamine can be mistaken for anesthetic excitement. Low-
dose ketamine has potential use in depression (Rasmussen et al., 2013).

The onset and duration of an induction dose of ketamine are deter-
mined by the same distribution/redistribution mechanisms operant for all 
the other parenteral anesthetics. Ketamine is metabolized to norketamine 
by hepatic CYPs (mainly by 3A4; less by 2B6 and 2D9). Norketamine, with 
–20% of the activity of ketamine, is hydroxylated and excreted in urine and 
bile. Ketamine’s large volume of distribution and rapid clearance make it 
suitable for continuous infusion (see Table 21–1 and Figure 21–2).

**Side Effects**

**Nervous System.** Ketamine has indirect sympathomimetic activity and 
produces distinct behavioral effects. The ketamine-induced cataleptic 
state is accompanied by nystagmus with pupillary dilation, salivation,
lacrimation, and spontaneous limb movements with increased overall muscle tone. Patients are amnestic and unresponsive to painful stimuli. Ketamine produces profound analgesia, a distinct advantage over other parenteral anesthetics. Unlike other parenteral anesthetics, ketamine increases CBF and ICP with minimal alteration of cerebral metabolism. The effects of ketamine on CBF can be readily attenuated by the simultaneous administration of sedative-hypnotic agents.

Emergence delirium, characterized by hallucinations, vivid dreams, and delusions, is a frequent complication of ketamine that can result in serious patient dissatisfaction and can complicate postoperative management. Benzodiazepines reduce the incidence of emergence delirium.

**Cardiovascular System.** Unlike other anesthetics, induction doses of thiopental typically increase blood pressure, heart rate, and cardiac output. The cardiovascular effects are indirect and are most likely mediated by inhibition of both central and peripheral catecholamine reuptake. Ketamine has direct negative inotropic and vasodilating activity, but these effects usually are overwhelmed by the indirect sympathomimetic action. Thus, ketamine is a useful drug, along with etomidate, for patients at risk for hypotension during anesthesia. While not arrhythmogenic, ketamine increases myocardial O2 consumption and is not an ideal drug for patients at risk for myocardial ischemia.

**Respiratory System.** The respiratory effects of ketamine are perhaps the best indication for its use. Induction doses of ketamine produce small and transient decreases in minute ventilation, but respiratory depression is less severe than with other parenteral anesthetics. Ketamine is a potent bronchodilator and is particularly well suited for anesthetizing patients at high risk for bronchospasm.

**Barbiturates**

Barbiturates are derivatives of barbituric acid with either an oxygen or a sulfur at the 2-position (see Figure 21–1 and Chapters 17 and 19). The three barbiturates most commonly used in clinical anesthesia are sodium thiopental (not currently marketed in the U.S.), thiamylal (currently licensed in the U.S. only for veterinary use), and methohexital. Sodium thiopental was used most frequently for inducing anesthesia.

Barbiturates are supplied as racemic mixtures despite enantioselectivity in their anesthetic potency. Barbiturates are formulated as the sodium salts with 6% sodium carbonate and reconstituted in water or isotonic saline to alkaline solutions, 10 < pH <11. Mixing barbiturates with drugs in acidic solutions during anesthetic induction can result in precipitation of the barbiturate as the free acid; thus, standard practice is to delay the administration of other drugs until the barbiturate has cleared the intravenous tubing.

The pharmacological properties and other therapeutic uses of the barbiturates are presented in Chapter 18. Table 19–3 lists the common barbiturates with their clinical pharmacological properties.

**Clinical Use and ADME.** Recommended intravenous dosing for parenteral barbiturates in a healthy young adult is given in Table 21–1. The availability of thiopental is limited currently by the lack of an FDA-licensed product and the prohibition of its import due to controversy over its use in administration of the death penalty by lethal injection.

The principal mechanism limiting anesthetic duration after single doses is redistribution of these hydrophobic drugs from the brain to other tissues. However, after multiple doses or infusions, the duration of action of the barbiturates varies considerably depending on their clearances. See Table 21–1 for pharmacokinetic parameters.

Methohexital differs from the other two intravenous barbiturates in its much more rapid clearance; thus, it accumulates less during prolonged infusions. Because of their slow elimination and large volumes of distribution, prolonged infusions or very large doses of thiopental and thiamylal can produce unconsciousness lasting several days. All three barbiturates are primarily eliminated by hepatic metabolism and subsequent renal excretion of inactive metabolites; a small fraction of thiopental undergoes desulfuration to the longer-acting hypnotic pentobarbital. Hepatic disease or other conditions that reduce serum protein concentrations will increase the initial free concentration and hypnotic effect of an induction dose.

**Side Effects**

**Nervous System.** Barbiturates suppress the EEG and can produce EEG burst suppression. They reduce the CMR, as measured by CMRo2, in a dose-dependent manner. As a consequence of the decrease in CMRo2, CBF and ICP are similarly reduced. Presumably, their CNS depressant activity contributes to their anticonvulsant effects (see Chapter 17). Methohexital can increase ictal activity, and seizures have been described in patients who received doses sufficient to produce burst suppression of the EEG, properties that make methohexital a good choice for anesthesia in patients who undergo electroconvulsive therapy.

**Cardiovascular System.** The anesthetic barbiturates produce dose-dependent decreases in blood pressure. The effect is due primarily to vasodilation, particularly venodilation, and to a lesser degree to a direct decrease in cardiac contractility. Typically, heart rate increases as a compensatory response to a lower blood pressure, although barbiturates also blunt the baroreceptor reflex. Thiopental maintains the ratio of myocardial O2 supply to demand in patients with coronary artery disease within a normal blood pressure range. Hypotension can be severe in patients with an impaired ability to compensate for venodilation, such as those with hypovolemia, cardiomyopathy, valvular heart disease, coronary artery disease, cardiac tamponade, or β adrenergic blockade. None of the barbiturates has been shown to be arrhythmogenic.

**Respiratory System.** Barbiturates are respiratory depressants. Induction doses of thiopental decrease minute ventilation and tidal volume, with a smaller and inconsistent decrease in respiratory rate. Reflex responses to hypercarbia and hypoxia are diminished by anesthetic barbiturates; at higher doses or in the presence of other respiratory depressants such as opiates, apnea can result. Compared to propofol, barbiturates produce a higher incidence of wheezing in asthmatics, attributed to histamine release from mast cells during induction of anesthesia.

**Other Side Effects.** Short-term administration of barbiturates has no clinically significant effect on the hepatic, renal, or endocrine systems. True allergies to barbiturates are rare; however, direct drug-induced histamine release is occasionally seen. Barbiturates can induce fatal attacks of porphyria in patients with acute intermittent or variegate porphyria and are contraindicated in such patients. Methohexital can produce pain on injection to a greater degree than thiopental. Inadvertent intra-arterial injection of thiobarbiturates can induce a severe inflammatory and potentially necrotic reaction that can threaten limb survival. Methohexital, and to a lesser degree other barbiturates, can produce excitatory symptoms on induction, such as cough, hiccup, muscle tremors, twitching, and hypertonus.

**Inhalational Anesthetics**

A wide variety of gases and volatile liquids can produce anesthesia. The structures of the currently used inhalational anesthetics are shown in Figure 21–3. The inhalational anesthetics have therapeutic indices (LD50/ED50) that range from 2 to 4, making these among the most dangerous drugs in clinical use. The toxicity of these drugs is largely a function of their side effects, and each of the inhalational anesthetics has a unique side-effect profile. Hence, the selection of an inhalational anesthetic often is based on balancing a patient’s pathophysiology with drug side-effect profiles.

Table 21–3 lists the widely varying physical properties of the inhalational agents in clinical use. Ideally, an inhalational agent would produce rapid induction of anesthesia and rapid recovery following discontinuation.

**Pharmacokinetic Principles**

Inhalational agents behave as gases rather than as liquids and thus require different pharmacokinetic constructs to be used in analyzing their uptake and distribution. Inhalational anesthetics distribute between tissues (or between blood and gas) such that equilibrium is achieved when the partial pressure of anesthetic gas is equal in the two tissues. When a person has breathed an inhalational anesthetic for a sufficiently long time that all tissues are equilibrated with the anesthetic, the partial pressure of the anesthetic in all tissues will be equal to the partial pressure of the anesthetic in inspired gas. While the partial pressure of the anesthetic may be equal in all tissues, the concentration of anesthetic in each tissue will be different.
Indeed, anesthetic partition coefficients are defined as the ratio of anesthetic concentration in two tissues when the partial pressures of anesthetic are equal in the two tissues. Blood:gas, brain:blood, and fat:blood partition coefficients for the various inhalational agents are listed in Table 21–3. These partition coefficients show that inhalational anesthetics are more soluble in some tissues (e.g., fat) than they are in others (e.g., blood). In clinical practice, equilibrium is achieved when the partial pressure in inspired gas is equal to the partial pressure in end-tidal (alveolar) gas. For inhalational agents that are not very soluble in blood or any other tissue, equilibrium is achieved quickly, as illustrated for nitrous oxide in Figure 21–4. If an agent is more soluble in a tissue such as fat, equilibrium may take many hours to reach. This occurs because fat represents a huge anesthetic reservoir that will be filled slowly because of the modest blood flow to fat. Anesthesia is produced when anesthetic partial pressure in brain is equal to or greater than MAC. Because the brain is well perfused, anesthetic partial pressure in brain becomes equal to the partial pressure in alveolar gas (and in blood) over the course of several minutes. Therefore, anesthesia is achieved shortly after alveolar partial pressure reaches MAC.

Elimination of inhalational anesthetics is largely a reversal of uptake. For inhalational agents with high blood and tissue solubility, recovery will be a function of the duration of anesthetic administration. This occurs because the accumulated amounts of anesthetic in the fat reservoir will prevent blood (and therefore alveolar) partial pressures from falling rapidly. Patients will be arousable when alveolar partial pressure reaches MAC$_{awake}$, a partial pressure somewhat lower than MAC (see Table 21–3).

### Specific Inhalational Agents

#### Isoflurane

Isoflurane is a volatile liquid at room temperature and is neither flammable nor explosive in mixtures of air or O$_2$. Isoflurane is a commonly used inhalational anesthetic worldwide.

**Clinical Use and ADME.** Isoflurane is typically used for maintenance of anesthesia after induction with other agents because of its pungent odor. Induction of anesthesia can be achieved in less than 10 min with an inhaled concentration of 1.5%–3% isoflurane in O$_2$; this concentration is reduced to 1%–2% (~1–2 MAC) for maintenance of anesthesia. The use of adjunct agents such as opioids or nitrous oxide reduces the concentration of isoflurane required for surgical anesthesia.

Isoflurane has a blood:gas partition coefficient substantially lower than that of enflurane. Consequently, induction with isoflurane and recovery from isoflurane are relatively faster. More than 99% of inhaled isoflurane is excreted unchanged by the lungs. Isoflurane does not appear to be a mutagen, teratogen, or carcinogen.

**Side Effects**

- **Cardiovascular System.** Isoflurane produces a concentration-dependent decrease in arterial blood pressure; cardiac output is well maintained; hypotension is the result of decreased systemic vascular resistance. Isoflurane produces vasodilation in most vascular beds, with pronounced effects in skin and muscle, and is a potent coronary vasodilator, simultaneously producing increased coronary blood flow and decreased myocardial O$_2$ consumption. Isoflurane significantly attenuates baroreceptor function. Patients anesthetized with isoflurane generally have mildly elevated heart rates as a compensatory response to reduced blood pressure; however, rapid changes in isoflurane concentration can produce both transient tachycardia and hypertension due to isoflurane-induced sympathetic stimulation.

- **Respiratory System.** Isoflurane produces concentration-dependent depression of ventilation. This drug is particularly effective at depressing the ventilatory response to hypercapnia and hypoxia. Although isoflurane is a bronchodilator, it also is an airway irritant and can stimulate airway reflexes during induction of anesthesia, producing coughing and laryngospasm.

$^a$MAC values are expressed as volume percent, the percentage of the atmosphere that is anesthetic. An MAC value greater than 100% means that hyperbaric conditions would be required.

$^b$MAC$_{awake}$ is the concentration at which appropriate responses to commands are lost.

$^c$EC$_{50}$ for memory suppression (vol%): isoflurane, 0.24; N$_2$O, 52.5; values not available for other agents.
Prolonged gas flow through the absorbent. The reaction of sevoflurane with soda lime produces decomposition products that may be toxic, such as inorganic fluoride. Interaction of sevoflurane also produces hexafluoroisopropanol. Hepatic metabolism of absorbed sevoflurane is metabolized by hepatic CYP2E1, with the predominant metabolic product being compound A, pentafluoroisopropenyl fluoromethyl ether (see kidney discussion under Side Effects).

**Side Effects**

**Cardiovascular System.** Sevoflurane produces concentration-dependent decreases in arterial blood pressure (due to systemic vasodilatation) and cardiac output. Sevoflurane does not produce tachycardia and thus may be a preferable agent in patients prone to myocardial ischemia.

**Respiratory System.** Sevoflurane produces a concentration-dependent reduction in tidal volume and increase in respiratory rate in spontaneously breathing patients. The increased respiratory frequency does not compensate for reduced tidal volume, with the net effect being a reduction in minute ventilation and an increase in Paco2. Sevoflurane is not irritating to the airway and is a potent bronchodilator. As a result, sevoflurane is the most effective clinical bronchodilator of the inhalational anesthetics.

**Nervous System.** Sevoflurane produces effects on cerebral vascular resistance, CMR02, and CBF that are similar to those produced by isoflurane and desflurane. Sevoflurane can increase ICP in patients with poor intracranial compliance, the response to hypocapnia is preserved during sevoflurane anesthesia, and increases in ICP can be prevented by hyperventilation. In children, sevoflurane is associated with delirium on emergence from anesthesia. This delirium is short lived and without any reported adverse long-term sequelae.

**Muscle.** Sevoflurane produces skeletal muscle relaxation and enhances the effects of nondepolarizing and depolarizing neuromuscular blocking agents.

**Kidney.** Controversy has surrounded the potential nephrotoxicity of compound A, which is produced by interaction of sevoflurane with the CO2 absorbent soda lime. Biochemical evidence of transient renal injury has been reported in human volunteers (Eger et al., 1997). Large clinical studies have shown no evidence of increased serum creatinine, blood urea nitrogen, or any other evidence of renal impairment following sevoflurane administration. The FDA recommends that sevoflurane be administered with fresh gas flows of 1–2 L/min, with sevoflurane exposures not exceeding 3 MAC-hours to minimize exposure to compound A.

**Liver and GI Tract.** Sevoflurane is not known to cause hepatotoxicity or alterations of hepatic function tests.

**Desflurane**

Desflurane is a highly volatile liquid at room temperature (vapor pressure = 669 mm Hg) and must be stored in tightly sealed bottles. Delivery of a precise concentration of desflurane requires the use of a specially heated vaporizer that delivers pure vapor that then is diluted appropriately with fresh gas flows of 1–2 L/min, with desflurane exposures not exceeding 3 MAC-hours to minimize exposure to compound A.

**Clinical Use and ADME.** Desflurane is for outpatient surgery because of its rapid onset of action and rapid recovery time. The drug irritates the tracheobronchial tree and can provoke coughing, salivation, and bronchospasm. Anesthesia therefore usually is induced with an intravenous agent, with desflurane subsequently administered for maintenance of anesthesia. Maintenance of anesthesia usually requires inhaled concentrations of 6%–8% (1 MAC). Lower concentrations of desflurane are required if it is coadministered with nitrous oxide or opioids.

Desflurane has a very low blood-gas partition coefficient (0.42) and also is not very soluble in fat or other peripheral tissues. Thus, the alveolar and blood concentrations rapidly rise to the level of inspired concentration, providing rapid induction of anesthesia and rapid changes in depth of anesthesia following changes in the inspired concentration. Emergence from desflurane anesthesia also is rapid. Desflurane is minimally metabolized; more than 99% of absorbed desflurane is eliminated unchanged through the lungs.

**Side Effects**

**Cardiovascular System.** Desflurane produces hypotension primarily by decreasing systemic vascular resistance. Cardiac output is well preserved, as is blood flow to the major organ beds (splanchnic, renal, cerebral, and coronary) (Eger, 1994). Transient tachycardia is often noted with abrupt increases in desflurane's delivered concentration, a result of this
desflurane-induced stimulation of the sympathetic nervous system. The hypotensive effects of desflurane do not wane with increasing duration of administration.

**Respiratory System.** Desflurane causes a concentration-dependent increase in respiratory rate and a decrease in tidal volume. At low concentrations (<1 MAC), the net effect is to preserve minute ventilation. Desflurane concentrations greater than 1 MAC depress minute ventilation, resulting in elevated arterial CO₂ tension (Paco₂). Desflurane is a bronchodilator. However, it also is a strong airway irritant and can cause coughing, breath-holding, laryngospasm, and excessive respiratory secretions. Because of its irritant properties, desflurane is not used as the primary anesthetic for induction of anesthesia.

**Nervous System.** Desflurane decreases cerebral vascular resistance and CMRO₂. Burst suppression of the EEG is achieved with ~2 MAC; at this level, CMRO₂ is reduced by ~50%. Under conditions of normocapnia and normotension, desflurane produces an increase in CBF and can increase ICP in patients with poor intracranial compliance. The vasoconstrictive response to hypocapnia is preserved during desflurane anesthesia, and increases in ICP thus can be prevented by hyperventilation.

**Muscle, Kidney, Liver, and GI Tract.** Desflurane produces direct skeletal muscle relaxation as well as enhances the effects of nondepolarizing and depolarizing neuromuscular blocking agents. Consistent with its minimal metabolic degradation, desflurane has no reported nephrotoxicity or hepatotoxicity.

**Desflurane and Carbon Monoxide.** Inhaled anesthetics are administered via a system that permits unidirectional flow of gas and rebreathing of exhaled gases. To prevent rebreathing of CO₂ (which can lead to hypercarbia), CO₂ absorbers are incorporated into the anesthesia delivery circuits. With almost complete desiccation of the CO₂ absorbents, substantial quantities of carbon monoxide can be produced. This effect is greatest with desflurane and can be prevented by the use of well-hydrated, fresh CO₂ absorbent.

**Halothane**

Halothane is a volatile liquid at room temperature and must be stored in a sealed container. Because halothane is a light-sensitive compound, it is marketed in amber bottles with thymol added as a preservative. Mixtures of halothane with O₂ or air are neither flammable nor explosive.

**Clinical Use and ADME.** Halothane has been used for maintenance of anesthesia. Concerns over hepatic toxicity have limited its use in developed countries. Halothane can produce fulminant hepatic necrosis (halothane hepatitis) in ~1 in 10,000 patients receiving halothane and “is referred to as halothane hepatitis” (“Summary,” 1966). This syndrome (with a 50% fatality rate) is characterized by fever, anorexia, nausea, and vomiting, developing several days after anesthesia, and can be accompanied by a rash and peripheral eosinophilia. Halothane hepatitis may be the result of an immune response to hepatic proteins that become trifluoroacetylated as a consequence of halothane metabolism. Halothane has a low cost and is still widely used in developing countries. Due to its side-effect profile and the availability of safer agents with more favorable pharmacokinetic profiles, halothane is no longer marketed in the U.S. Those interested in further information on halothane should consult previous recent editions of this book.

**Enflurane**

Enflurane is a clear, colorless liquid at room temperature and has a mild, sweet odor. Like other inhalational anesthetics, it is volatile and must be stored in a sealed bottle. It is nonflammable and nonexplosive in mixtures of air or oxygen.

**Clinical Use and ADME.** Enflurane is primarily utilized for maintenance rather than induction of anesthesia. Surgical anesthesia can be induced with enflurane in less than 10 min with an inhaled concentration of 2%–4.5% in oxygen and maintained with concentrations from 0.5% to 3%. Enflurane concentrations required to produce anesthesia are reduced when it is coadministered with nitrous oxide or opioids. Concerns over enflurane’s ability to decrease seizure threshold and potentially produce nephrotoxicity have limited its clinical utility in developed countries (Mazze et al., 1977).

Because of its relatively high blood-gas partition coefficient, induction of anesthesia and recovery from enflurane are relatively slow. Enflurane is metabolized to a modest extent, with 2%–8% of absorbed enflurane undergoing oxidative metabolism by hepatic CYP2E1. Fluoride ions are a by-product of enflurane metabolism, but plasma fluoride levels are low and nontoxic. Patients taking isoniazid exhibit enhanced metabolism of enflurane with consequent elevation of serum fluoride.

**Side Effects.** Enflurane causes a decrease in arterial blood pressure, the result of vasodilation and depression of myocardial contractility, with minimal effects on heart rate. The drug is an effective bronchodilator and produces a pattern of rapid shallow breathing. Due to its actions as a cerebral vasodilator, enflurane can increase ICP. It can produce seizure activity and should not be used in patients with seizure disorders. Enflurane relaxes skeletal and uterine muscle. As with other anesthetic gases, enflurane reduces renal blood flow, GFR, and urinary output.

**Nitrous Oxide**

Nitrous oxide is a colorless, odorless gas at room temperature. N₂O is sold in steel cylinders and must be delivered through calibrated flowmeters provided on all anesthesia machines. N₂O is neither flammable nor explosive, but it does support combustion as actively as oxygen does when it is present in proper concentration with a flammable anesthetic or material.

**Clinical Use and ADME.** N₂O is a weak anesthetic agent that has significant analgesic effects. Surgical anesthetic depth is only achieved under hyperbaric conditions. By contrast, analgesia is produced at concentrations as low as 20%. The analgesic property of N₂O is a function of the activation of opioidergic neurons in the periaqueductal gray matter and the adrenergic neurons in the locus ceruleus. N₂O is frequently used in concentrations of ~50% to provide analgesia and mild sedation in outpatient dentistry. N₂O cannot be used at concentrations above 80% because this limits the delivery of adequate O₂. Because of this limitation, N₂O is used primarily as an adjunct to other inhalational or intravenous anesthetics.

Nitrous oxide is very insoluble in blood and other tissues. This results in rapid equilibration between delivered and alveolar anesthetic concentrations and provides for rapid induction of anesthesia and rapid emergence following discontinuation of administration. The rapid uptake of N₂O from alveolar gas serves to concentrate coadministered halogenated anesthetics; this effect (the “second gas effect”) speeds induction of anesthesia. On discontinuation of N₂O administration, N₂O gas can diffuse from blood to the alveoli, diluting O₂ in the lung. This can produce an effect called diffusion hypoxia. To avoid hypoxia, 100% O₂ rather than air should be administered when N₂O is discontinued. Almost all (99.9%) of the absorbed N₂O is eliminated unchanged by the lungs.

**Side Effects**

**Cardiovascular System.** Although N₂O produces a negative inotropic effect on heart muscle in vitro, depressant effects on cardiac function generally are not observed in patients because of the stimulatory effects of N₂O on the sympathetic nervous system. The cardiovascular effects of N₂O also are heavily influenced by the concomitant administration of other anesthetic agents. When N₂O is coadministered with halogenated inhalational anesthetics, one observes increases in heart rate, arterial blood pressure, and cardiac output. In contrast, when N₂O is coadministered with an opioid, one generally sees decreases in arterial blood pressure and cardiac output. N₂O also increases venous tone in both the peripheral and the pulmonary vasculature. The effects of N₂O on pulmonary vascular resistance can be exaggerated in patients with preexisting pulmonary hypertension; thus, the drug generally is not used in these patients.

**Respiratory System.** N₂O causes modest increases in respiratory rate and decreases in tidal volume in spontaneously breathing patients. Even modest concentrations of N₂O markedly depress the ventilatory response to hypoxia. Thus, it is prudent to monitor arterial O₂ saturation directly in patients receiving or recovering from N₂O.

**Nervous System.** N₂O can significantly increase CBF and ICP. This cerebral vasodilatory capacity of N₂O is significantly attenuated by the simultaneous administration of intravenous agents such as opiates and propofol. By contrast, the combination of N₂O and inhaled agents results
in greater vasodilation than the administration of the inhaled agent alone at equivalent anesthetic depth.

**Muscle.** N₂O does not relax skeletal muscle and does not enhance the effects of neuromuscular blocking drugs.

**Kidney, Liver, and GI Tract.** N₂O is not known to have nephrotoxic or hepatotoxic effects.

**Other Adverse Effects.** A major problem with N₂O is that it will exchange with N₂ in any air-containing cavity in the body. Moreover, because of their differential blood-gas partition coefficients, N₂O will enter the cavity faster than N₂ escapes, thereby increasing the volume or pressure in this cavity. Examples of air collections that can be expanded by N₂O include a pneumothorax, an obstructed middle ear, an air embolus, an obstructed loop of bowel, an intracranial air bubble, a pulmonary bulla, and intracranial air. N₂O should be avoided in these clinical settings.

Nitrous oxide interacts with the covalent bond of vitamin B₁₂, thereby preventing vitamin B₁₂ from acting as a cofactor for methionine synthase (Sanders and Maze, 2007). Inactivation of methionine synthase can produce signs of vitamin B₁₂ deficiency, including megaloblastic anemia and peripheral neuropathy, a particular concern in patients with malnutrition, vitamin B₁₂ deficiency, or alcoholism. The clinical use of N₂O is controversial due to its potential metabolic effects related to increased homocysteine and changes in DNA and protein synthesis (Ko et al., 2014). For this reason, N₂O is not used as a chronic analgesic or as a sedative in critical care settings.

**Xenon**

Xenon, an inert gaseous element, is not approved for use in the U.S. and is unlikely to enjoy widespread use because it is a rare gas that cannot be manufactured and must be extracted from air; thus, xenon is expensive and available in limited quantities. Xenon, unlike other anesthetic agents, has minimal cardiorespiratory and other side effects.

Xenon exerts its anaglytic and anesthetic effects at a number of receptor systems in the CNS. Of these, noncompetitive antagonism of the NMDA receptor and agonism at the TREK channel (a member of the two-pore K⁺ channel family) are thought to be the central mechanisms of xenon action (Franks and Honore, 2004).

Xenon is extremely insoluble in blood and other tissues, providing for rapid induction and emergence from anesthesia. It is sufficiently potent to produce surgical anesthesia when administered with 30% oxygen. However, supplementation with an intravenous agent such as propofol appears to be required for clinical anesthesia. Xenon is well tolerated in patients of advanced age. No long-term side effects from xenon anesthesia have been reported.

### Anesthetic Adjuncts

A general anesthetic is usually given with adjuncts to augment specific components of anesthesia, permitting lower doses of general anesthetics with fewer side effects.

### Benzodiazepines

Benzodiazepines (see Chapters 15 and 19) can produce anesthesia similar to that of barbiturates; they are more commonly used for sedation rather than general anesthesia because prolonged amnesia and sedation may result from anesthetizing doses. As adjuncts, benzodiazepines are used for anxiolysis, amnesia, and sedation prior to induction of anesthesia or for sedation during procedures not requiring general anesthesia. The benzodiazepine most frequently used in the perioperative period is midazolam, followed distantly by diazepam and lorazepam.

Midazolam is water soluble and typically is administered intravenously but also can be given orally, intramuscularly, or rectally; oral midazolam is particularly useful for sedation of young children. Midazolam produces minimal venous irritation (as opposed to diazepam and lorazepam, which are formulated in propylene glycol and are painful on injection, sometimes producing thrombophlebitis). Midazolam has the pharmacokinetic advantage, particularly over lorazepam, of being more rapid in onset and shorter in duration of effect. Sedative doses of midazolam (0.01–0.05 mg/kg IV) reach peak effect in about 2 min and provide sedation for approximately 30 min. Elderly patients tend to be more sensitive to and have a slower recovery from benzodiazepines. Midazolam is metabolized principally by hepatic CYP3A4, and drug interactions with inducers, inhibitors, and substrates of that CYP are predictable. Either for prolonged sedation or for general anesthetic maintenance, midazolam is more suitable than other benzodiazepines for infusion, although midazolam's duration of action (t₁/₂) does significantly increase with prolonged infusions (see Figure 21–2). Benzodiazepines reduce CBF and cerebral metabolism, but at equianesthetic doses are less effective than barbiturates in this respect. Benzodiazepines modestly decrease blood pressure and respiratory drive, occasionally resulting in apnea.

### Analgesics

Analgesics typically are administered with general anesthetics to reduce anesthetic requirements and minimize hemodynamic changes produced by painful stimuli. Nonsteroidal anti-inflammatory drugs, cyclooxygenase 2 inhibitors, and acetaminophen (see Chapter 38) sometimes provide adequate analgesia for minor surgical procedures. However, opioids are the primary analgesics used during the perioperative period because of the rapid and profound analgesia they produce. Fentanyl, sufentanil, alfentanil, remifentanil, meperidine, and morphine are the major parenteral opioids used in the perioperative period. The primary analgesic activity of each of these drugs is produced by agonist activity at μ opioid receptors (see Chapter 20).

The choice of a perioperative opioid is based primarily on duration of action because, at appropriate doses, all produce similar analgesia and side effects. Remifentanil has an ultrashort duration of action (<10 min), accumulates minimally with repeated doses, and is particularly well suited for procedures that are briefly painful. Single doses of fentanyl, sufentanil, and alfentanil all have similar intermediate durations of action (30, 20, and 15 min, respectively), but recovery after prolonged administration varies considerably. Fentanyl's duration of action lengthens the most with infusion, sufentanil's much less so, and alfentanil's the least.

Fentanyl's duration of action lengthens the most with infusion, sufentanil's much less so, and alfentanil's the least.

The frequency and severity of nausea, vomiting, and pruritus after emergence from anesthesia are increased by all opioids to about the same degree. A useful side effect of meperidine is its capacity to reduce shivering, a common problem during emergence from anesthesia; other opioids are not as efficacious against shivering, perhaps due to less κ receptor agonism. Finally, opioids often are administered intrathecally and epidurally for management of acute and chronic pain (see Chapter 20). Neuromuscular opioids with or without local anesthetics can provide profound analgesia for many surgical procedures; however, respiratory depression and pruritus usually limit their use to major operations.

### Neuronal Blocking Agents

The practical aspects of the use of neuromuscular blockers as anesthetic adjuncts are briefly described here. The detailed pharmacology of this drug class is presented in Chapter 11.
Depolarizing (e.g., succinylcholine) and nondepolarizing (e.g., vecuronium) muscle relaxants often are administered during the induction of anesthesia to relax muscles of the jaw, neck, and airway and thereby facilitate laryngoscopy and endotracheal intubation. Nondepolarizing muscle relaxants are generally better tolerated. Barbiturates will precipitate when mixed with muscle relaxants and should be allowed to clear from the intravenous line prior to injection of a muscle relaxant. The action of nondepolarizing muscle relaxants usually is antagonized, once muscle paralysis is no longer desired, with an acetylcholinesterase inhibitor such as neostigmine or edrophonium (see Chapter 10), in combination with a muscarinic receptor antagonist (e.g., glycopyrrolate or atropine; see Chapter 9) to offset the muscarinic activation resulting from esterase inhibition. Sugammadex, a first-in-class selective relaxant binding agent specific for reversal of rocuronium muscle-relaxing effect, is approved in Europe and awaits FDA approval in the U.S. (Ledowski, 2015).

### Anesthetic Toxicity and Cytoprotection

The conventional view of general anesthesia is that anesthetics produce a reversible loss of consciousness and that CNS function returns to basal levels on termination of anesthesia and recovery of anesthesia. Recent data, however, cast doubt on this notion. Exposure of rodents to anesthetic agents during the period of synaptogenesis results in widespread neurodegeneration in the developing brain (Jevtovic-Todorovic et al., 2003). This neuronal injury resulted in disturbed electrophysiologic function and cognitive dysfunction in adolescent and adult rodents exposed to anesthetics during the neonatal period. The cognitive deficits attendant with neonatal anesthetic exposure have been attributed to neuronal apoptosis; however, recently published data have cast doubt on this premise. There is convincing data that exposure to anesthetics in the neonatal period leads to activation of “classical” preconditioning pathways, including isoflurane, propofol, midazolam, nitrous oxide, and thiopental, manifest this toxicity (Patel and Sun, 2009). The underlying mechanism(s) in animal models are unclear, and the threat to humans is still uncertain.

By contrast, anesthetics reduce ischemic injury to a variety of tissues, including the heart and brain. This protective effect is robust and results in better functional outcomes in comparison to ischemic injury that occurs in the unanesthetized awake subjects. In the brain, several mechanisms for anesthetic-mediated protection have been proposed, including suppression of excitotoxicity from excess glutamate release, reduction in inflammation, and increased prosurvival signaling (Head and Patel, 2007). In the heart, the molecular mechanisms attendant to anesthetic-mediated protection include activation of “classical” pre-conditioning pathways, including GPCRs, endothelial NO synthases, survival protein kinases, PKC, reactive oxygen species, ATP-dependent K+ channels, and the mitochondrial permeable transition pore (Kunst and Klein, 2015).

### Therapeutic Gases

#### Oxygen

Oxygen is essential to life. Hypoxia is a life-threatening condition in which O2 delivery is inadequate to meet the metabolic demands of the tissues. Hypoxia may result from alterations in tissue perfusion, decreased O2 tension in the blood, or decreased O2 carrying capacity. In addition, hypoxia may result from restricted O2 transport from the microvasculature to cells or impaired utilization within the cell. An inadequate supply of O2 ultimately results in the cessation of aerobic metabolism and oxidative phosphorylation, depletion of high-energy compounds, cellular dysfunction, and death.

**Normal Oxygenation**

Oxygen makes up 21% of air, which at sea level represents a partial pressure of 21 kPa (158 mm Hg). While the fraction (percentage) of O2 remains constant regardless of atmospheric pressure, the P02 decreases with lower atmospheric pressure. Ascent to elevated altitude reduces the uptake and delivery of O2 to the tissues, whereas increases in atmospheric pressure (e.g., hyperbaric therapy or breathing at depth) raise the P02, in inspired air and increase gas uptake. As the air is delivered to the distal airways and alveoli, the P02 decreases by dilution with CO2 and water vapor and by uptake into the blood.

Under ideal conditions, when ventilation and perfusion are well matched, the alveolar P02 will be about 14.6 kPa (110 mm Hg). The corresponding alveolar partial pressures of water and CO2 are 6.2 kPa (47 mm Hg) and 5.3 kPa (40 mm Hg), respectively. Under normal conditions, there is complete equilibration of alveolar gas and lung capillary blood, and the P02 in end-capillary blood is typically within a fraction of a kilopascal of that in the alveoli. The P02 in arterial blood, however, is further reduced by venous admixture (shunt), the addition of mixed venous blood from the pulmonary artery, which has a P02 of about 5.3 kPa (40 mm Hg). Together, the diffusional barrier, ventilation-perfusion mismatches, and the shunt fraction are the major causes of the alveolar-to-arterial O2 gradient, which is normally 1.3–1.6 kPa (10–12 mm Hg) when air is breathed and 4.0–6.6 kPa (30–50 mm Hg) when 100% O2 is breathed. O2 is delivered to the tissue capillary beds by the circulation and again follows a gradient out of the blood and into cells. Tissue extraction of O2 typically reduces the P02 of venous blood by an additional 7.3 kPa (55 mm Hg). Although the P02 at the site of cellular O2 utilization—the mitochondria—is not known, oxidative phosphorylation can continue at a P02 of only a few millimeters of mercury.

In the blood, O2 is carried primarily in chemical combination with hemoglobin and is to a small extent dissolved in solution. The quantity of O2 combined with hemoglobin depends on the P02, as illustrated by the sigmoidal oxyhemoglobin dissociation curve (Figure 21–5). Hemoglobin is about 98% saturated with O2 when air is breathed under normal circumstances, and it binds 1.3 mL of O2 per gram when fully saturated. The steep slope of this curve with falling P02 facilitates unloading of O2 from hemoglobin at the tissue level and reloading when desaturated mixed venous blood arrives at the lung. Shifting of the curve to the right with increasing temperature, increasing Pco2, and decreasing pH, as is found in metabolically active tissues, lowers the O2 saturation for the same P02 and thus delivers additional O2 to where and when it is most needed. However, the flattening of the curve with higher P02 indicates that increasing blood PO2 by inspiring O2-enriched mixtures can increase the amount of O2 carried by hemoglobin only minimally. Because of the low solubility of O2 (0.226 mL/L per kPa or 0.03 mL/L per mm Hg at 37°C), breathing 100% O2 can increase the amount of O2 dissolved in blood by only 15 mL/L, less than one-third of normal metabolic demands. However, if the inspired PO2 is increased to 3 atm (304 kPa) in a hyperbaric chamber, the amount of dissolved O2 is sufficient to meet normal metabolic demands even in the absence of hemoglobin (Table 21–4).

#### Oxygen Deprivation

**Hypoxemia** generally implies a failure of the respiratory system to oxygenate arterial blood. Classically, there are five causes of hypoxemia:

- **Low Fio2**
- **Hypoventilation**
- **Ventilation-perfusion mismatch**
- **Shunt or venous admixture**
- **Increased diffusion barrier**

The term hypoxia denotes insufficient oxygenation of the tissues. In addition to failure of the respiratory system to oxygenate the blood adequately, a number of other factors can contribute to hypoxia at the tissue level. These may be divided into categories of O2 delivery and O2 utilization. O2 delivery decreases globally when cardiac output falls or locally when regional blood flow is compromised, such as from a vascular occlusion (e.g., stenosis, thrombosis, or microvascular occlusion) or increased downstream pressure (e.g., compartment syndrome, venous stasis, or venous hypertension). Decreased O2 carrying capacity of the blood likewise will reduce O2 delivery, such as occurs with anemia, carbon monoxide poisoning, or hemoglobinopathy. Finally, hypoxia may occur when
transport of O₂ from the capillaries to the tissues is decreased (edema) or utilization of the O₂ by the cells is impaired (CN⁻ toxicity).

**Effects of Hypoxia**

**Cellular and Metabolic Effects.** At the molecular level, nonlethal hypoxia produces a marked alteration in gene expression, mediated in part by hypoxia inducible factor 1α (Guimarães-Camboa et al., 2015). When the mitochondrial Po₂ falls below about 0.13 kPa (1 mm Hg), aerobic metabolism stops, and the less-efficient anaerobic pathways of glycolysis become responsible for the production of cellular energy. End products of anaerobic metabolism, such as lactic acid, are released into the circulation in measurable quantities. Energy-dependent ion pumps slow, and transmembrane ion gradients dissipate. Intracellular concentrations of Na⁺, Ca²⁺, and H⁺ increase, finally leading to cell death. The time course of cellular demise depends on the relative metabolic demands, oxygen storage capacity, and anaerobic capacity of the individual organs. Restoration of perfusion and oxygenation prior to hypoxic cell death paradoxically can result in an accelerated form of cell injury (ischemia-reperfusion syndrome), which is thought to result from the generation of highly reactive oxygen free radicals.

**Cell and Organ Survival.** Ultimately, hypoxia results in the cessation of aerobic metabolism, exhaustion of high-energy intracellular stores, cellular dysfunction, and death. The time course of cellular demise depends on the tissue’s relative metabolic requirements, O₂ and energy stores, and anaerobic capacity. Survival times (the time from the onset of circulatory arrest to significant organ dysfunction) range from 1–2 min in the cerebral cortex to around 5 min in the heart and 10 min in the kidneys and liver, with the potential for some degree of recovery if reperfused. Revival times (the duration of hypoxia beyond which recovery is no longer possible) are about four to five times longer.

**Organ System Effects.** Less-severe degrees of hypoxia have progressive physiological effects on different organ systems (Nunn, 2005).

- **Respiratory System.** Hypoxia stimulates the carotid and aortic baroreceptors to cause increases in both the rate and the depth of ventilation. Minute volume almost doubles when normal individuals inspire gas with a Po₂ of 6.6 kPa (50 mm Hg). Dyspnea is not always experienced with simple hypoxia but occurs when the respiratory minute volume approaches half the maximal breathing capacity; this may occur with minimum exertion in patients in whom maximal breathing capacity is reduced by lung disease. In general, little warning precedes the loss of consciousness resulting from hypoxia.

- **Cardiovascular System.** Hypoxia causes reflex activation of the sympathetic nervous system by both autonomic and humoral mechanisms, resulting in tachycardia and increased cardiac output. Peripheral vascular resistance, however, decreases primarily through local autoregulatory mechanisms, with the net result that blood pressure generally is maintained unless hypoxia is prolonged or severe. In contrast to the systemic circulation, hypoxia causes pulmonary vasoconstriction and hypertension, an extension of the normal regional vascular response that matches perfusion with ventilation to optimize gas exchange in the lung (hypoxic pulmonary vasoconstriction).

**CNS.** The CNS is least able to tolerate hypoxia. Hypoxia is manifest initially by decreased intellectual capacity and impaired judgment and psychomotor ability. This state progresses to confusion and restlessness and ultimately to stupor, coma, and death as the arterial Po₂ decreases below 4–5.3 kPa (30–40 mm Hg). Victims often are unaware of this progression.

*This table illustrates the carriage of oxygen in the blood under a variety of circumstances. As arterial O₂ tension increases, the amount of dissolved O₂ increases in direct proportion to the Po₂, but the amount of oxygen bound to Hb reaches a maximum of 196 mL O₂/L (100% saturation of Hb at 15 g/dL). Further increases in O₂ content require increases in dissolved oxygen. At 100% inspired O₂, dissolved O₂ still provides only a small fraction of total demand. Hyperbaric oxygen therapy is required to increase the amount of dissolved oxygen to supply all or a large part of metabolic requirements. Note that, during hyperbaric oxygen therapy, the hemoglobin in the mixed venous blood remains fully saturated with O₂. The figures in this table are approximate and are based on the assumptions of 15 g/dL Hb, 50 mL O₂/L whole-body oxygen extraction, and constant cardiac output. When severe anemia is present, arterial Po₂ remains the same, but arterial content is lower; oxygen extraction continues, resulting in lower O₂ content and tension in mixed venous blood. Similarly, as cardiac output falls significantly, the same oxygen extraction occurs from a smaller volume of blood and results in lower mixed venous oxygen content and tension.*
Adaptation to Hypoxia

Long-term hypoxia results in adaptive physiological changes; these have been studied most thoroughly in persons exposed to high altitude. Adaptations include increased numbers of pulmonary alveoli, increased concentrations of hemoglobin in blood and myoglobin in muscle, and a decreased ventilatory response to hypoxia. Short-term exposure to high altitude produces similar adaptive changes. In susceptible individuals, however, acute exposure to high altitude may produce acute mountain sickness, a syndrome characterized by headache, nausea, dyspnea, sleep disturbances, and impaired judgment progressing to pulmonary and cerebral edema. Mountain sickness is treated with rest and analgesics when mild or supplemental O₂ descent to lower altitude, or an increase in ambient pressure when more severe. Acetazolamide (a carbonic anhydrase inhibitor) and dexamethasone also may be helpful. The syndrome usually can be avoided by a slow ascent to altitude, adequate hydration, and prophylactic use of acetazolamide or dexamethasone.

Examples of “normal” hypoxia are widespread, and the comparative physiologic of hypoxic tolerance offers clues to the mechanisms involved. Aspects of fetal and newborn physiology are strongly reminiscent of adaptation mechanisms found in hypoxia-tolerant animals (Guimarães-Camboa et al., 2015; Mortola, 1999), including shifts in the oxyhemoglobin dissociation curve (fetal hemoglobin), reductions in metabolic rate and body temperature (hibernation-like mode), reductions in heart rate and circulatory redistribution (as in diving mammals), and redirection of energy utilization from growth to maintenance metabolism. These adaptations probably account for the relative tolerance of the fetus and neonate to both chronic (uterine insufficiency) and short-term hypoxia.

Oxygen Inhalation

Physiological Effects. O₂ inhalation is used primarily to reverse or prevent the development of hypoxia. However, when O₂ is breathed in excessive amounts or for prolonged periods, secondary physiological changes and toxic effects can occur.

Respiratory System. Inhalation of O₂ at 1 atm or above causes a small degree of respiratory depression in normal subjects, presumably as a result of loss of tonic chemoreceptor activity. However, ventilation typically increases within a few minutes of O₂ inhalation because of a paradoxical increase in the tension of CO₂ in tissues. This increase results from the increased concentration of oxyhemoglobin in venous blood, which causes less-efficient removal of carbon dioxide from the tissues. Expansion of poorly ventilated alveoli is maintained in part by the nitrogen content of alveolar gas; nitrogen is poorly soluble and thus remains in the air spaces poorly ventilated alveoli is maintained in part by the nitrogen content of alveolar gas; nitrogen is poorly soluble and thus remains in the air spaces during the expansion of poorly ventilated alveoli. High O₂ concentrations delivered to poorly ventilated lung regions dilute the nitrogen content and can promote absorption atelectasis (partial or complete collapse of the lung), occasionally resulting in an increase in shunt and a paradoxical worsening of hypoxemia after a period of O₂ administration.

Cardiovascular System. Heart rate and cardiac output are slightly reduced when 100% O₂ is breathed; blood pressure changes little. Elevated pulmonary artery pressures in patients living at high altitude who have chronic hypoxic pulmonary hypertension may reverse with O₂ therapy or return to sea level. In neonates with congenital heart disease and left-to-right shunting of cardiac output, O₂ supplementation must be regulated carefully because of the risk of further reducing pulmonary vascular resistance and increasing pulmonary blood flow.

Metabolism. Inhalation of 100% O₂ does not produce detectable changes in O₂ consumption, CO₂ production, respiratory quotient, or glucose utilization.

Oxygen Administration

Oxygen is supplied as a compressed gas in steel cylinders; purity of 99% is medical grade. For safety, O₂ cylinders and piping are color coded (green in the U.S.), and some form of mechanical indexing of valve connections is used to prevent the connection of other gases to O₂ systems.

Oxygen is delivered by inhalation except during extracorporeal circulation, when it is dissolved directly into the circulating blood. A closed delivery system with an endotracheal tube produces an airtight seal to the patient’s airway, and complete separation of inspired from expired gases can precisely control Fio₂. In all other systems, such as nasal cannulas and face masks, the actual delivered Fio₂ will depend on the ventilatory pattern (i.e., rate, tidal volume, inspiratory-expiratory time ratio, and inspiratory flow) and delivery system characteristics.

Monitoring of Oxygenation. Monitoring and titration are required to meet the therapeutic goal of O₂ therapy and to avoid complications and side effects. Although cyanosis is a physical finding of substantial clinical importance, it is not an early, sensitive, or reliable index of oxygenation. Noninvasive monitoring of arterial O₂ saturation can be achieved using transcutaneous pulse oximetry, in which O₂ saturation is measured from the differential absorption of light by oxyhemoglobin and deoxyhemoglobin and the arterial saturation determined from the insoluble component of this signal. Pulse oximetry measures hemoglobin saturation and not PO₂. It is not sensitive to increases in PO₂ that exceed levels required to saturate the blood fully. Pulse oximetry is useful for monitoring the adequacy of oxygenation during procedures requiring sedation or anesthesia, rapid evaluation and monitoring of potentially compromised patients, and titrating O₂ therapy in situations where toxicity from O₂ or side effects of excess O₂ are of concern. A specific tool for measuring cerebral oxygenation is near-infrared spectroscopy (Guarracino, 2008).

Complications of Oxygen Therapy. In addition to the potential to promote absorption atelectasis and depression ventilation, high flows of dry O₂ can dry out and irritate mucosal surfaces of the airway and the eyes, as well as decrease mucociliary transport and clearance of secretions. Humidified O₂ thus should be used when prolonged therapy (>1 h) is required. Finally, any O₂-enriched atmosphere constitutes a fire hazard, and appropriate precautions must be taken. Hypoxemia can occur despite the administration of supplemental O₂. Therefore, it is essential that both O₂ saturation and adequacy of ventilation be assessed frequently.

Therapeutic Uses of Oxygen

Correction of Hypoxia. The primary therapeutic use of O₂ is to correct hypoxia. Hypoxia is most frequently the manifestation of an underlying disease, and administration of O₂ thus should be viewed as temporizing therapy. Efforts must be directed at correcting the cause of the hypoxia. Hypoxia resulting from most pulmonary diseases can be alleviated at least partially by administration of O₂, allowing time for definitive therapy to reverse the primary process.

Reduction of Partial Pressure of an Inert Gas. Because nitrogen constitutes some 79% of ambient air, it also is the predominant gas in most gas-filled spaces in the body. In situations such as bowel distension from obstruction or ileus, intravascular air embolism, or pneumothorax, it is desirable to reduce the volume of air-filled spaces. Because nitrogen is relatively insoluble, inhalation of high concentrations of O₂ (and thus low concentrations of nitrogen) rapidly lowers the total-body partial pressure of nitrogen and provides a substantial gradient for the removal of nitrogen from gas spaces. Administration of O₂ for air embolism is also beneficial because it helps to relieve localized hypoxia distal to the vascular obstruction. In the case of decompression sickness, or bends, lowering the inert gas tension in blood and tissues by O₂ inhalation prior to or during barometric decompression reduces the supersaturation that occurs after decompression so that bubbles do not form.

Hyperbaric Oxygen Therapy. O₂ can be administered at greater than atmospheric pressure in hyperbaric chambers (Thom, 2009). Clinical uses of hyperbaric O₂ therapy include the treatment of trauma, burns, radiation damage, infections, nonhealing ulcers, skin grafts, spasticity, and other neurological conditions. Hyperbaric O₂ may be useful in generalized hypoxia. In carbon monoxide poisoning, hemoglobin and myoglobin become unavailable for O₂ binding because of the high affinity of these proteins for carbon monoxide. High P0₂ facilitates competition of O₂ for hemoglobin binding sites as carbon monoxide is exchanged in the alveoli. In addition, hyperbaric O₂ increases the availability of dissolved O₂ in the blood (see Table 21-4). Adverse effects of hyperbaric O₂ therapy include middle ear barotrauma, CNS toxicity, seizures, lung toxicity, and aspiration pneumonia.
Hyperbaric O₂ therapy has two components: increased hydrostatic pressure and increased O₂ pressure. Both factors are necessary for the treatment of decompression sickness and air embolism. The hydrostatic pressure reduces bubble volume, and the absence of inspired nitrogen increases the gradient for elimination of nitrogen and reduces hypoxia in downstream tissues. Increased O₂ pressure at the tissue is the primary therapeutic goal for other indications for hyperbaric O₂. A small increase in PₐO₂ in ischemic areas enhances the bactericidal activity of leukocytes and increases angiogenesis. Repetitive brief exposures to hyperbaric O₂ may enhance therapy for chronic refractory osteomyelitis, osteoradionecrosis, crush injury, or the recovery of compromised skin and tissue grafts. Increased O₂ tension can be bacteriostatic and useful in the treatment of the spread of infection with Clostridium perfringens and clostridial myonecrosis (gas gangrene).

**Oxygen Toxicity**

Oxygen can have deleterious actions at the cellular level. O₂ toxicity may result from increased production of hydrogen peroxide and reactive intermediates such as superoxide anion, singlet oxygen, and hydroxyl radicals that attack and damage lipids, proteins, and other macromolecules, especially those in biological membranes. A number of factors limit the toxicity of oxygen-derived reactive agents, including enzymes such as superoxide dismutase, glutathione peroxidase, and catalase, which scavenge toxic oxygen by-products, and reducing agents such as iron, glutathione, and ascorbate. These factors, however, are insufficient to limit the destructive actions of oxygen when patients are exposed to high concentrations over an extended time period. Tissues show differential sensitivity to oxygen toxicity, which is likely the result of differences in both their production of reactive compounds and their protective mechanisms.

**Respiratory Tract.** The pulmonary system is usually the first to exhibit toxicity, a function of its continuous exposure to the highest O₂ tensions in the body. Subtle changes in pulmonary function can occur within 8–12 h of exposure to 100% O₂. Increases in capillary permeability, which will increase the alveolar/arterial O₂ gradient and ultimately lead to further hypoxemia, and decreased pulmonary function can be seen after only 18 h of exposure. Serious injury and death, however, require much longer exposures. Pulmonary damage is directly related to the inspired O₂ tension, and concentrations of less than 0.5 atm appear to be safe over long time periods. The capillary endothelium is the most sensitive tissue of the lung. Endothelial injury results in loss of surface area from interstitial edema and leaks into the alveoli.

**Nervous System.** Retinopathy of prematurity is an eye disease in premature infants involving abnormal vascularization of the developing retina that can result from O₂ toxicity or relative hypoxia. CNS problems are rare, and toxicity occurs only under hyperbaric conditions where exposure exceeds 200 kPa (2 atm). Symptoms include seizures and visual changes, which resolve when O₂ tension is returned to normal. In premature neonates and those who have sustained in utero asphyxia, hypoxia and hypopcapnia are associated with worse neurologic outcomes.

**Carbon Dioxide**

Carbon dioxide is produced by metabolism at approximately the same rate as O₂ is consumed. At rest, this value is about 3 mL/kg/min, but it may increase dramatically with exercise. CO₂ diffuses readily from the tissue or the inhalation of CO₂, whereas an increase in ventilation results in decreased Pco₂ and respiratory alkalosis. Because CO₂ is freely diffusible, the changes in blood Pco₂ and pH soon are reflected by intracellular changes in Pco₂ and pH and by widespread effects in the body, especially on respiration, circulation, and the CNS.

**Respiration**

Carbon dioxide is a rapid, potent stimulus to ventilation in direct proportion to the inspired CO₂. CO₂ stimulates breathing by acidifying central chemoreceptors and the peripheral carotid bodies. Elevated Pco₂ causes bronchodilation, whereas hypocarbia causes constriction of airway smooth muscle; these responses may play a role in matching pulmonary ventilation and perfusion.

**Circulation**

The circulatory effects of CO₂ result from the combination of its direct local effects and its centrally mediated effects on the autonomic nervous system. The direct effect of CO₂ on the heart, diminished contractility, results from pH changes and a decreased myofilament Ca²⁺ responsiveness. The direct effect on systemic blood vessels results in vasodilation. CO₂ causes widespread activation of the sympathetic nervous system. The results of sympathetic nervous system activation generally are opposite to the local effects of carbon dioxide. The sympathetic effects consist of increases in cardiac contractility, heart rate, and vasoconstriction (see Chapter 12). The balance of opposing local and sympathetic effects, therefore, determines the total circulatory response to CO₂. The net effect of CO₂ inhalation is an increase in cardiac output, heart rate, and blood pressure. In blood vessels, however, the direct vasodilating actions of CO₂ appear more important, and total peripheral resistance decreases when the Pco₂ is increased. CO₂ also is a potent coronary vasodilator. Cardiac arrhythmias associated with increased Pco₂ are due to the release of catecholamines.

**Hypocarbia** results in opposite effects: decreased blood pressure and vasoconstriction in skin, intestine, brain, kidney, and heart. These actions are exploited clinically in the use of hyperventilation to diminish intracranial hypertension.

**CNS**

Hypocarbia depresses the excitability of the cerebral cortex and increases the cutaneous pain threshold through a central action. This central depression has therapeutic importance. For example, in patients who are hyperventilating from narcotics or anesthetics, increasing Pco₂ may result in further CNS depression, which in turn may worsen the respiratory depression. This positive-feedback cycle can have lethal consequences.

**Methods of Administration**

Carbon dioxide is marketed in gray metal cylinders as the pure gas or as CO₂ mixed with O₂. It is usually administered at a concentration of 5–10% in combination with O₂ by means of a face mask. Another method for the temporary administration of CO₂ is by rebreathing, such as from an anesthesia breathing circuit or from something as simple as a paper bag.

**Therapeutic Uses**

Carbon dioxide is used for insufflation during endoscopic procedures (e.g., laparoscopic surgery) because it is highly soluble and does not support combustion. CO₂ can be used to flood the surgical field during cardiac surgery. Because of its density, CO₂ displaces the air surrounding the open heart so that any gas bubbles trapped in the heart are CO₂ rather than insoluble N₂. It is used to adjust pH during cardiopulmonary bypass procedures when a patient is cooled.

Hypocarbia still has some uses in anesthesia; it constricts cerebral vessels, decreasing brain size slightly, and thus may facilitate the performance of neurosurgical operations. While short-term hypocarbia is effective for this purpose, sustained hypocarbia has been associated with worse outcomes in patients with head injury. Hypocarbia should be instituted with a clearly defined indication and normocapnia should be reestablished as soon as the indication for hypocarbia no longer applies.

**Nitric Oxide**

Nitric oxide is a free-radical gas now known as a critical endogenous cell-signaling molecule with an increasing number of potential therapeutic applications.
Endogenous NO is produced from L-arginine by NO synthases (neural, inducible, and endothelial) (see Chapter 3). In the vasculature, basal production of NO by endothelial cells is a primary determinant of resting vascular tone. NO causes vasodilatation of smooth muscle cells and inhibition of platelet aggregation and adhesion. Impaired NO production is implicated in atherosclerosis, hypertension, cerebral and coronary vasospasm, ischemia-reperfusion injury, and inflammation and in mediating central nociceptive pathways. NO is rapidly inactivated in the circulation by oxyhemoglobin and by the reaction of NO with the heme iron, leading to the formation of nitrosyl-hemoglobin. Small quantities of methemoglobin are also produced, and these are converted to the ferrous form of heme iron by cytochrome b5 reductase. The majority of inhaled NO is excreted in the urine in the form of nitrate.

**Therapeutic Uses**

Inhaled NO selectively dilates the pulmonary vasculature (Cooper, 1999) and has potential as a therapy for numerous diseases associated with increased pulmonary vascular resistance. Inhaled NO is FDA-approved for only one indication, persistent pulmonary hypertension of the newborn.

**Diagnostic Uses**

Inhaled NO can be used during cardiac catheterization to evaluate the pulmonary vasodilating capacity of patients with heart failure and infants with congenital heart disease. Inhaled NO also is used to determine the diffusion capacity (Dl) across the alveolar-capillary unit. NO is more effective than CO2 in this regard because of its greater affinity for hemoglobin and its higher water solubility at body temperature. NO is produced from the nasal passages and from the lungs of normal human subjects and can be detected in exhaled gas. The measurement of fractional exhaled NO is a noninvasive marker for airway inflammation with utility in the assessment of respiratory tract diseases, including asthma, respiratory tract infection, and chronic lung disease.

**Toxicity**

Administered at low concentrations (0.1–50 ppm), inhaled NO appears to be safe and without significant side effects. Pulmonary toxicity can occur with levels higher than 50–100 ppm. NO is an atmospheric pollutant; the Occupational Safety and Health Administration places the 7-hour exposure limit at 50 ppm. Part of the toxicity of NO may be related to its further oxidation to NO2 in the presence of high concentrations of O2.

The development of methemoglobinemia is a significant complication of inhaled NO at higher concentrations, and rare deaths have been reported with overdoses of NO. Methemoglobin concentrations should be monitored intermittently during NO inhalation. Inhaled NO can inhibit platelet function and has been shown to increase bleeding time in some clinical studies, although bleeding complications have not been reported. In patients with impaired function of the left ventricle, NO has a potential to further impair left ventricular performance by dilating the pulmonary circulation and increasing the blood flow to the left ventricle, thereby increasing left atrial pressure and promoting pulmonary edema.

The most important requirements for safe NO inhalation therapy include the following:

- Continuous measurement of NO and NO2 concentrations using either chemiluminescence or electrochemical analyzers
- Frequent calibration of monitoring equipment
- Intermittent analysis of blood methemoglobin levels

**Methods of Administration**

Courses of treatment with inhaled NO are highly varied, extending from 0.1 to 40 ppm in dose and for periods of a few hours to several weeks in duration. The determination of a dose-response relationship on a frequent basis should assist in the titration of the optimum dose of NO. Commercial NO systems are available that will accurately deliver inspired NO concentrations between 0.1 and 80 ppm and simultaneously measure NO and NO2 concentrations.

**Helium**

Helium is an inert gas whose low density, low solubility, and high thermal conductivity provide the basis for its medical and diagnostic uses. Helium can be mixed with O2 and administered by mask or endotracheal tube. Under hyperbaric conditions, it can be substituted for the bulk of other gases, resulting in a mixture of much lower density that is easier to breathe.

The primary uses of helium are in pulmonary function testing, the treatment of respiratory obstruction, laser airway surgery, as a label in imaging studies, and for diving at depth. Helium is also suited for determinations of residual lung volume, functional residual capacity, and related lung volumes. These measurements require a highly diffusible nontoxic gas that is insoluble and does not leave the lung by the bloodstream so that, by dilution, the lung volume can be measured. Helium can be added to O2 to reduce turbulence due to airway obstruction because the density of helium is less than that of air, and the viscosity of helium is greater than that of air. Mixtures of helium and O2 reduce the work of breathing. Helium has high thermal conductivity, making it useful during laser surgery on the airway. Laser-polarized helium is used as an inhalational contrast agent for pulmonary magnetic resonance imaging. Helium also has potential as a cytoprotective agent (Smit et al., 2015).

**Hydrogen Sulfide**

Hydrogen sulfide, which has a characteristic rotten egg smell, is a colorless, flammable, water-soluble gas that is primarily considered as a toxin due to its capacity to inhibit mitochondrial respiration through blockade of cytochrome c oxidase. Inhibition of respiration can be toxic; however, if depression of respiration occurs in a controlled manner, it may allow nonhibernating species exposed to inhaled H2S to enter a state akin to suspended animation (i.e., a slowing of cellular activity to a point at which metabolic processes are inhibited but not terminal) and thereby increase tolerance to stress. H2S activates ATP-dependent K+ channels, has vasodilating properties, and serves as a free-radical scavenger. H2S can protect against whole-body hypoxia, lethal hemorrhage, and ischemia-reperfusion injury in various organs, including the kidney, lung, liver, and heart. Currently, effort is under way for development of gas-releasing molecules that could deliver H2S and other therapeutic gases to diseased tissue. H2S in low quantities may have the potential to limit cell death (Lefer, 2007).

### Anesthetic Adjuncts - Augment anesthetic effects of general anesthesia (continued)

**Analgesics**

**Opioids**
- To reduce anesthetic requirement and minimize hemodynamic changes due to painful stimuli
- Opioids are the primary analgesics during perioperative period; the choice of opioid is based on duration of action (see Chapter 20)
- Opioids often are administered intrathecally and epidurally for management of acute and chronic pain

**NSAIDs**
- Acetaminophen
- NSAIDs and acetaminophen are used for minor surgical procedures to control postoperative pain

**Neuromuscular Blocking Agents**
- Succinylcholine (Depolarizing)
- Atracurium, Vecuronium, et al. (Nondepolarizing, Competitive)
- Action of nondepolarizing muscle relaxants usually is antagonized, once muscle paralysis is no longer desired, with an ACHE inhibitor (e.g., neostigmine or edrophonium; see Chapter 10), in combination with a muscarinic receptor antagonist

### THERAPEUTIC GASES

**Oxygen**
- Used primarily to reverse or prevent the development of hypoxia
- Excessive O₂ ⇒ ventilation
- Monitoring and titration are required to avoid complications and side effects
- HR and CO are slightly ↓ when 100% O₂ is breathed
- High flows of dry O₂ can dry out and irritate mucosal surfaces of the airway and the eyes; humidified O₂ should be used with prolonged therapy (≥1 h)
- O₂-enriched atmosphere constitutes a fire hazard; take precautions

**Carbon dioxide**
- Insufflation during endoscopic procedures
- Flooding the surgical field during cardiac surgery
- Adjusting pH during cardiopulmonary bypass
- CO₂ is highly soluble, noncombustible, denser than air.
- ↑ PCO₂ ⇒ respiratory acidosis
- Effects on CV system: combination of direct CNS and reflex sympathetic effects; net effect: ↑ in CO, HR, and BP

**Nitric oxide**
- Inhaled NO is used to dilate pulmonary vasculature in persistent pulmonary hypertension of the newborn
- Cell-signaling molecule; induces vasodilation
- Pulmonary toxicity can occur with levels > 50-100 ppm
- Use lowest NO concentration required for therapeutic effect
- Monitor blood methemoglobin levels intermittently during inhalation therapy

**Helium**
- Pulmonary function testing, treatment of respiratory obstruction, laser airway surgery
- As a label in imaging studies
- Mixtures of He and O₂ reduce the work of breathing
- Potential as a cytoprotective agent
- For diving at depth

**Hydrogen sulfide**
- Potential therapeutic use for protection against effects of hypoxia

---

### Bibliography

Summary of the National Halothane Study. Possible association between halothane anesthesia and postoperative hepatic necrosis. *JAMA*, 1966, 197:775–788.
Local anesthetics bind reversibly to a specific receptor site within the pore of the Na⁺ channels in nerves and block ion movement through this pore. When applied locally to nerve tissue in appropriate concentrations, local anesthetics can act on any part of the nervous system and on every type of nerve fiber, reversibly blocking the action potentials responsible for nerve conduction. Thus, a local anesthetic in contact with a nerve trunk can cause both sensory and motor paralysis in the area innervated. These effects of clinically relevant concentrations of local anesthetics are reversible with recovery of nerve function and no evidence of damage to nerve fibers or cells in most clinical applications.

### History

The first local anesthetic, cocaine, was serendipitously discovered to have anesthetic properties in the late 19th century. Cocaine occurs in abundance in the leaves of the coca shrub (*Erythroxylon coca*). For centuries, Andean natives have chewed an alkali extract of these leaves for its stimulatory and euphoric actions. When, in 1860, Albert Niemann isolated cocaine, he tasted his newly isolated compound, noted that it numbed his tongue, and a new era began. Sigmund Freud studied cocaine’s physiological actions, and Carl Koller introduced cocaine into clinical practice in 1884 as a topical anesthetic for ophthalmological surgery. Shortly thereafter, Halstead popularized its use in infiltration and conduction block anesthesia.

### Chemistry and Structure-Activity Relationship

Cocaine is an ester of benzoic acid and the complex alcohol 2-carbomethoxy, 3-hydroxytropane (Figure 22–1). Because of its toxicity and addictive properties (Chapter 24), a search for synthetic substitutes for cocaine began in 1892 with the work of Einhorn and colleagues, resulting in the synthesis of procaine, which became the prototype for local anesthetics for nearly half a century. The most widely used agents today are lidocaine, bupivacaine, and tetracaine.

Typical local anesthetics contain hydrophobic and hydrophobic moieties that are separated by an intermediate ester or amide linkage. A broad range of compounds containing these minimal structural features can satisfy the requirements for action as local anesthetics. The hydrophilic group usually is a tertiary amine but also may be a secondary amine; the hydrophobic moiety must be aromatic. The nature of the linking group determines some of the pharmacological properties of these agents. For example, plasma esterases readily hydrolyze local anesthetics with an ester link.

The structure-activity relationship and the physicochemical properties of local anesthetics have been well reviewed (Courtney and Strichartz, 1987). Hydrophobicity increases both the potency and the duration of action of the local anesthetics; association of the drug at hydrophobic sites enhances the partitioning of the drug to its sites of action and decreases the rate of metabolism by plasma esterases and hepatic enzymes. In addition, the receptor site for these drugs on Na⁺ channels is thought to be hydrophobic (see Mechanism of Action), so that receptor affinity for anesthetic agents is greater for the more hydrophobic drugs. Hydrophobicity also increases toxicity, so that the therapeutic index is decreased for more hydrophobic drugs.

Molecular size influences the rate of dissociation of local anesthetics from their receptor sites. Smaller drug molecules can escape from the receptor site more rapidly. This characteristic is important in rapidly firing cells, in which local anesthetics bind during action potentials and dissociate during the period of membrane repolarization. Rapid binding of local anesthetics during action potentials causes the frequency and voltage dependence of their action.
Local anesthetics act at the cell membrane to prevent the generation and the conduction of nerve impulses. Conduction block can be demonstrated in squid giant axons from which the axoplasm has been removed.

Local anesthetics block conduction by decreasing or preventing the large transient increase in the permeability of excitable membranes to Na⁺ that normally is produced by a slight depolarization of the membrane (Chapters 8, 11, and 14; Strichartz and Ritchie, 1987). This action of local anesthetics is due to their direct interaction with voltage-gated Na⁺ channels. As the anesthetic action progressively develops in a nerve, the threshold for electrical excitability gradually increases, the rate of rise of the action potential declines, impulse conduction slows, and the safety factor for conduction decreases. These factors decrease the probability of propagation of the action potential, and nerve conduction eventually fails.

Local anesthetics can bind to other membrane proteins (Butterworth and Strichartz, 1990). In particular, they can block K⁺ channels (Strichartz and Ritchie, 1987). However, because the interaction of local anesthetics with K⁺ channels requires higher concentrations of drug, blockade of conduction is not accompanied by any large or consistent change in resting membrane potential.

Quaternary analogues of local anesthetics block conduction when applied internally to perfused giant axons of squid but are relatively ineffective when applied externally. These observations suggest that the site at which local anesthetics act, at least in their charged form, is accessible only from the inner surface of the membrane (Narahashi and Frazier, 1971; Strichartz and Ritchie, 1987). Therefore, local anesthetics applied externally first must cross the membrane before they can exert a blocking action.

The Local Anesthetic Receptor Site on Na⁺ Channels

The major mechanism of action of these drugs involves their interaction with one or more specific binding sites within the Na⁺ channel (Butterworth and Strichartz, 1990). The Na⁺ channels of the mammalian brain are complexes of glycosylated proteins with an aggregate molecular size in excess of 300,000 Da; the individual subunits are designated α (260,000 Da) and β1 to β4 (33,000–38,000 Da). The large α subunit of the Na⁺ channel contains four homologous domains (I–IV); each domain is thought to consist of six transmembrane segments in α-helical conformation (S1–S6; Figure 22–2) and an additional, membrane-reentrant pore (P) loop. The Na⁺-selective transmembrane pore of the channel resides in the center of a nearly symmetrical structure formed by the four homologous domains. The voltage dependence of channel opening is hypothesized to reflect conformational changes that result from the movement of “gating charges” within the voltage sensor module of the sodium channel in response to changes in the transmembrane potential. The gating charges are located in the S4 transmembrane helices, which are hydrophobic and positively charged, containing lysine or arginine residues at every third position. These residues are thought to move perpendicular to the plane of the membrane under the influence of the transmembrane potential, initiating a series of conformational changes in all four domains, which leads to the open state of the channel (Figure 22–2) (Catterall, 2000; Yu et al., 2005).

The transmembrane pore of the Na⁺ channel is surrounded by the SS and S6 transmembrane helices and the short membrane-associated segments between them that form the P loop. Amino acid residues in these short segments are the most critical determinants of the ion conductance and selectivity of the channel.

After it opens, the Na⁺ channel inactivates within a few milliseconds due to closure of an inactivation gate. This functional gate is formed by the short intracellular loop of protein that connects homologous domains III and IV.
**Figure 22–2 Structure and function of voltage-gated Na⁺ channels.** A. A two-dimensional representation of the α (center), β₁ (left), and β₂ (right) subunits of the voltage-gated Na⁺ channel from mammalian brain. The polypeptide chains are represented by continuous lines with length approximately proportional to the actual length of each segment of the channel protein. Cylinders represent regions of transmembrane α helices. ψ indicates sites of demonstrated N-linked glycosylation. Note the repeated structure of the four homologous domains (I–IV) of the α subunit. **Voltage Sensing.** The S4 transmembrane segments in each homologous domain of the α subunit serve as voltage sensors. (+) represents the positively charged amino acid residues at every third position within these segments. Electrical field (negative inside) exerts a force on these charged amino acid residues, pulling them toward the intracellular side of the membrane; depolarization allows them to move outward and initiate a conformational change that opens the pore. **Pore.** The S5 and S6 transmembrane segments and the short membrane-associated loop between them (P loop) form the walls of the pore in the center of an approximately symmetrical square array of the four homologous domains (see B). The amino acid residues indicated by circles in the P loop are critical for determining the conductance and ion selectivity of the Na⁺ channel and its ability to bind the extracellular pore-blocking toxins TTX and saxitoxin. **Inactivation.** The short intracellular loop connecting homologous domains III and IV serves as the inactivation gate of the Na⁺ channel. It is thought to fold into the intracellular mouth of the pore and occlude it within a few milliseconds after the channel opens. Three hydrophobic residues (IFM) at the position marked h appear to serve as an inactivation particle, entering the intracellular mouth of the pore and binding therein to an inactivation gate receptor there. **Modulation.** The gating of the Na⁺ channel can be modulated by protein phosphorylation. Phosphorylation of the inactivation gate between homologous domains III and IV by PKC slows inactivation. Phosphorylation of sites in the intracellular loop between homologous domains I and II by either PKC or PKA reduces Na⁺ channel activation. (Adapted with permission from Catterall WA. From ionic currents to molecular mechanisms: the structure and function of voltage-gated sodium channels. Neuron, 2000, 26:13–25. Copyright © Elsevier). B. The four homologous domains of the Na⁺ channel α subunit are illustrated as a square array, as viewed looking down on the membrane. The sequence of conformational changes that the Na⁺ channel undergoes during activation and inactivation is diagrammed. On depolarization, each of the four homologous domains sequentially undergoes a conformational change to an activated state. After all four domains have activated, the Na⁺ channel can open. Within a few milliseconds after opening, the inactivation gate between domains III and IV closes over the intracellular mouth of the channel and occludes it, preventing further ion conductance (see Catterall, 2000).

and IV. This loop folds over the intracellular mouth of the transmembrane pore during the process of inactivation and binds to an inactivation gate “receptor” formed by the intracellular mouth of the pore.

Amino acid residues important for local anesthetic binding are found in the S6 segments in domains I, III, and IV (Ragdale et al., 1994; Yarov-Yarovoy et al., 2002). Hydrophobic amino acid residues near the center and the intracellular end of the S6 segment may interact directly with bound local anesthetics, locating the local anesthetic receptor site in the intracellular half of the transmembrane pore of the Na⁺ channel, with part of its structure contributed by amino acids in the S6 segments of domains I, III, and IV (Figure 22–3). Ancestral Na⁺ channels in bacteria comprise four identical subunits, each similar to one of the four domains of the mammalian Na⁺ channel subunit and containing a similar voltage sensor and pore-lining segment. The three-dimensional structure of an ancestral
Figure 22–3  A pharmacologist’s view of the interaction of a local anesthetic with a voltage-gated Na⁺ channel. A voltage-gated Na⁺ channel may be thought of as an antechamber (extracellular funnel) that feeds into a constricted area (selectivity filter), which opens onto a larger volume (central cavity) that has an exit door (gate). Functionally, the channel can exist in a cycle of multiple states, initiated by the local effects of an action potential on the S4 transmembrane segments of the α subunits of segments I–IV, shown in Figure 22–2A. These states are resting/closed, intermediate/closed, open, inactivated. LA bind in the center of the region depicted by the light blue balls. LAs exist in charged and uncharged forms at physiological pH, in accordance with the Henderson-Hasselbalch relationship (Figure 2–2). The uncharged species, LA, can diffuse across the membrane, possibly interacting with the channel protein en route. Within the cell, LA equilibrates with H⁺; the charged form, LAH⁺, binds in the channel with greater affinity than does the uncharged species. The resting/closed conformation of the channel, in which the positive charges of the S4 segments are pulled toward the cell interior by the resting membrane potential, has a relatively low affinity for LA. The effect of an action potential is to initiate a conformational change in the selectivity funnel region of the channel, moving the positive charges outward and away from the pore interior. As a result, intermediate/closed, open, and inactivated states have a much higher affinity for LA. LAs prevent opening of the intermediate state, may block the channel in the open state, and extend the duration of the inactivated state. Ultimately, however, LA dissociates from its binding site (and the rate of LA’s dissociation affects the extent of channel block), and the receptor returns to the resting state. Thus, stimulation of a nerve by an action potential enhances LA binding. With a low frequency of stimulation, LA has time to dissociate and the channels reliably return to their resting state (low affinity for LA). With a high frequency of stimulation, as in nociceptive sensory afferents after a wound, there is insufficient time for LA to fully dissociate; thus, the fraction of channels liganded by LA increases in the continued presence of LA, leading to greater and greater conduction blockade, as explained in the text. The marine neurotoxin TTX binds in the funnel with high affinity (K_d = 10⁻¹⁰ nM), as does saxitoxin; both toxins block Na⁺ channel activity.

Frequency and Voltage Dependence

The degree of block produced by a given concentration of local anesthetic depends on how the nerve has been stimulated and on its resting membrane potential. Thus, a resting nerve is much less sensitive to a local anesthetic than one that is repetitively stimulated; higher frequency of stimulation and more positive membrane potential cause a greater degree of anesthetic block. These frequency- and voltage-dependent effects of local anesthetics occur because the charged form of the local anesthetic molecule gains access to its binding site within the pore primarily when the Na⁺ channel is open and because the local anesthetic binds more tightly to and stabilizes the inactivated state of the Na⁺ channel (Butterworth and Strichartz, 1990; Courtney and Strichartz, 1987; Hille, 1977). Remarkably, the conformation of the local anesthetic receptor site is changed considerably in the inactivated state (Payandeh et al., 2012; Figure 22–3D), revealing how preferential binding to inactivated Na⁺ channels may occur.

Local anesthetics exhibit frequency and voltage dependence to different extents depending on their pK_a, lipid solubility, molecular size, and binding to different channel states. In general, the frequency dependence of local anesthetic action depends critically on the rate of dissociation from the receptor site in the pore of the Na⁺ channel. A high frequency of stimulation is required for rapidly dissociating drugs so that drug binding during the action potential exceeds drug dissociation between
action potentials. Dissociation of smaller and more hydrophobic drugs is more rapid, so a higher frequency of stimulation is required to yield frequency-dependent block. Frequency-dependent block of ion channels is also important for the actions of antiarrhythmic drugs (Chapter 30).

**Differential Sensitivity of Nerve Fibers**

For most patients, treatment with local anesthetics causes the sensation of pain to disappear first, followed by loss of the sensations of temperature, touch, deep pressure, and finally motor function (Table 22–1). Classical experiments with intact nerves showed that the δ wave in the compound action potential, which represents slowly conducting, small-diameter myelinated fibers, was reduced more rapidly and at lower concentrations of cocaine than was the α wave, which represents rapidly conducting, large-diameter fibers (Gasser and Erlanger, 1929). In general, autonomic fibers, small unmyelinated C fibers (mediating pain sensations), and small myelinated Aδ fibers (mediating pain and temperature sensations) are blocked before the larger myelinated Aγ, Aβ, and Aα fibers (mediating postural, touch, pressure, and motor information) (Raymond and Gissen, 1987). The differential rate of block exhibited by fibers mediating different sensations is of considerable practical importance in the use of local anesthetics.

The precise mechanisms responsible for this apparent specificity of local anesthetic action on pain fibers are not known, but several factors may contribute. The initial hypothesis was that sensitivity to local anesthetic block increases with decreasing fiber size, consistent with high sensitivity for pain sensation mediated by small fibers and low sensitivity for motor function mediated by large fibers (Gasser and Erlanger, 1929). However, when nerve fibers are dissected from nerves to allow direct measurement of action potential generation, no clear correlation of the concentration dependence of local anesthetic block with fiber diameter is observed (Fink and Cairns, 1984; Franz and Perry, 1974; Huang et al., 1997). Therefore, it is unlikely that the fiber size per se determines the sensitivity to local anesthetic block under steady-state conditions. However, the spacing of nodes of Ranvier increases with the size of nerve fibers. Because a fixed number of nodes must be blocked to prevent conduction, small fibers with closely spaced nodes of Ranvier may be blocked more rapidly during treatment of intact nerves because the local anesthetic reaches a critical length of nerve more rapidly. Differences in tissue barriers and location of smaller C fibers and Aδ fibers in nerves also may influence the rate of local anesthetic action. Different combinations of Na+ channel subtypes are also expressed in these nerve fibers, but all of these Na+ channels have similar affinity for block by local anesthetics.

**Effect of pH**

Local anesthetics tend to be only slightly soluble as unprotonated amines. Therefore, they generally are marketed as water-soluble salts, usually hydrochlorides. Because local anesthetics are weak bases (typical pKₐ values range from 8 to 9), their hydrochloride salts are mildly acidic. This property increases the stability of the local anesthetic esters and the catecholamines added as vasoconstrictors. Under usual conditions of administration, the pH of the local anesthetic solution rapidly equilibrates to that of the extracellular fluids.

Although the unprotonated species of the local anesthetic is necessary for diffusion across cellular membranes, it is the cationic species that interacts preferentially with Na+ channels. The results of experiments on anesthetized mammalian nonmyelinated fibers support this conclusion (Ritchie and Greengard, 1966). In these experiments, conduction could be blocked or unblocked merely by adjusting the pH of the bathing medium to 7.2 or 9.6, respectively, without altering the amount of anesthetic present. The primary role of the cationic form also was demonstrated by Narahashi and Frazier, who perfused the extracellular and axoplasmic surface of the giant squid axon with tertiary and quaternary amine local anesthetics and found that the quaternary amines were active only when perfused intracellularly (Narahashi and Frazier, 1971). However, the unprotonated molecular forms also possess some anesthetic activity (Butterworth and Strichartz, 1990). Recent reports indicated that quaternary local anesthetics such as QX-314 can gain access to the cytoplasmic surface of the nerve cell membrane via TRPV1 channels (reviewed by Butterworth and Oxford, 2009). TRP channels, and possibly other ion channels, appear to lose selectivity and permit permeation of molecules like QX-314 in the face of prolonged or intense activation.

**Prolongation of Action by Vasoconstrictors**

The duration of action of a local anesthetic is proportional to the time of contact with nerve. Consequently, maneuvers that keep the drug at the nerve prolong the period of anesthesia. For example, cocaine inhibits the neuronal membrane transporters for catecholamines, thereby potentiating the effect of NE at α adrenergic receptors in the vasculature, resulting in vasoconstriction and reduced cocaine absorption in vascular beds where α adrenergic effects predominate (Chapters 8 and 12). In clinical practice,
Chapter 22

Sympathomimetic amines increase the O2 consumption of the tissue; this, together with hypotension, may result in necrosis after local anesthesia. These effects seem to occur partly because a large number of sympathetic nerve fibers innervate areas with limited collateral circulation is avoided.

Undesired Effects of Local Anesthetics

In addition to blocking conduction in nerve axons in the peripheral nervous system, local anesthetics interfere with the function of all organs in which conduction or transmission of impulses occurs. Thus, these agents affect the CNS, autonomic ganglia, neuromuscular junctions, and all forms of muscle (for a review, see Covino, 1987; Garfield and Gugino, 1987; Gintant and Hoffman, 1987). The danger of such adverse reactions is proportional to the concentration of local anesthetic achieved in the circulation. In general, local anesthetics with chiral centers, the S-enantiomer is less toxic than the R-enantiomer (McClure, 1996).

CNS

Following absorption, local anesthetics may cause CNS stimulation, producing restlessness and tremor that may progress to clonic convulsions. In general, the more potent the anesthetic, the more readily convulsions may be produced. Alterations of CNS activity are thus predictable from the local anesthetic agent in question and the blood concentration achieved. Central stimulation is followed by depression; death usually is caused by respiratory failure.

The apparent stimulation and subsequent depression produced by applying local anesthetics to the CNS presumably is due solely to depression of neuronal activity; a selective depression of inhibitory neurons likely accounts for the excitatory phase in vivo. Rapid systemic administration of local anesthetics may produce death with no or only transient signs of CNS stimulation. Under these conditions, the concentration of the drug probably rises so rapidly that all neurons are depressed simultaneously. Airway control, along with ventilatory and circulatory support, are essential features of treatment in the late stage of intoxication. Intravenously administered benzodiazepines are the drugs of choice for both the prevention and the arrest of convulsions. Neither propofol nor a rapidly acting barbiturate is preferred; both are more likely to produce cardiovascular depression than a benzodiazepine (Chapter 19).

Although drowsiness is the most frequent complaint that results from the CNS actions of local anesthetics, lidocaine may produce dysphoria or euphoria and muscle twitching. Moreover, lidocaine may produce a loss of consciousness that is preceded only by symptoms of sedation (Covino, 1987). Whereas other local anesthetics also show the effect, cocaine has a particularly prominent effect on mood and behavior. These effects of cocaine and its potential for abuse are discussed in Chapter 24.

Cardiovascular System

Following systemic absorption, local anesthetics act on the cardiovascular system. The primary site of action is the myocardium, where decreases in electrical excitability, conduction rate, and force of contraction occur. In addition, most local anesthetics cause arteriolar dilatation. Untoward cardiovascular effects usually are seen only after high systemic concentrations are attained and CNS symptoms are evident. However, on rare occasions, lower doses of some local anesthetics will cause cardiovascular collapse and death, probably due to either an action on the pacemaker or the sudden onset of ventricular fibrillation. Ventricular tachycardia and fibrillation are relatively uncommon consequences of local anesthetics other than bupivacaine. The antiarrhythmic effects of local anesthetics such as lidocaine and procainamide are discussed in Chapter 30. Finally, it should be stressed that untoward cardiovascular effects of local anesthetics may result from their inadvertent intravascular administration, especially if epinephrine is also present.

Smooth Muscle

Local anesthetics depress contractions in the intact bowel and in strips of isolated intestine (Zipf and Dittmann, 1971). They also relax vascular and bronchial smooth muscle, although low concentrations initially may produce contraction (Covino, 1987). Spinal and epidural anesthesia, as well as instillation of local anesthetics into the peritoneal cavity, cause sympathetic nervous system paralysis, which can result in increased tone of GI musculature (described under Clinical Uses). Local anesthetics may increase the resting tone and decrease the contractions of isolated human uterine muscle; however, uterine contractions are seldom depressed directly during intrapartum regional anesthesia.

Neuromuscular Junction and Ganglia

Local anesthetics also affect transmission at the neuromuscular junction. At concentrations at which the muscle responds normally to direct electrical stimulation, procaine can block the response of skeletal muscle to maximal motor-nerve volleys and to ACh. Similar effects occur at autonomic ganglia. These effects are due to block of nicotinic ACh receptors by high concentrations of the local anesthetic (Charnet et al., 1990; Neher and Steinbach, 1978).

Hypersensitivity

Rare individuals are hypersensitive to local anesthetics. The reaction may manifest itself as an allergic dermatitis or a typical asthmatic attack (Covino, 1987). It is important to distinguish allergic reactions from toxic side effects and from the effects of coadministered vasoconstrictors. Hypersensitivity seems to occur more frequently with local anesthetics of the ester type and frequently extends to chemically related compounds. For example, individuals sensitive to procaine also may react to structurally similar compounds (e.g., tetracaine) through reaction to a common metabolite. Although allergic responses to agents of the amide type are uncommon, solutions of such agents may contain preservatives such as methylparaben that may provoke an allergic reaction (Covino, 1987). Local anesthetic preparations containing a vasoconstrictor also may elicit allergic responses due to the sulfoxide added as an antioxidant for the catecholamine/vasoconstrictor.

Metabolism

Local anesthetics of the ester type (e.g., tetracaine) are hydrolyzed and inactivated primarily by a plasma esterase, probably plasma cholinesterase. The liver also participates in hydrolysis of local anesthetics. Because spinal fluid contains little or no esterase, anesthesia produced by the intrathecal injection of an anesthetic agent will persist until the local anesthetic agent has been absorbed into the circulation. The amide-linked local anesthetics are, in general, degraded by the hepatic CYPs, with the initial reactions involving N-dealkylation and subsequent hydrolysis (Arthur, 1987). However, with prilocaine, the initial step is hydrolytic, forming o-toluidine metabolites that can cause methemoglobinemia. The extensive use of amide-linked local anesthetics in patients with severe hepatic disease requires caution.

Toxicity

The metabolic fate of local anesthetics is of great practical importance because toxicity can result from an imbalance between their rates of absorption and elimination. The rate of absorption of many local anesthetics into...
the systemic circulation can be considerably reduced by the incorporation of a vasoconstrictor agent in the anesthetic solution. However, the rate of degradation of local anesthetics varies greatly, and this is a major factor in determining the safety of a particular agent. Because toxicity is related to the concentration of free drug, binding of the anesthetic to proteins in the serum and to tissues reduces toxicity. For example, in intravenous regional anesthesia of an extremity, about half of the original anesthetic dose still is tissue bound 30 min after the restoration of normal blood flow (Arthur, 1987). Reversing the effects of local anesthetic systemic toxicity is a clinical challenge. One developing approach is promising and unusual: intravenous lipid emulsion therapy (Weinberg, 2012). Whether the lipids simply provide a favorable milieu of micelles into which lipophilic drugs can partition or the effect involves more complex biochemical pathways is not yet clear (Fettplace et al., 2016).

Plasma binding sites serve to moderate local anesthetic levels on blood. The amide-linked local anesthetics bind extensively (55%–95%) to plasma proteins, particularly α1-acid glycoprotein. Many factors increase (e.g., cancer, surgery, trauma, myocardial infarction, smoking, and uremia) or decrease (e.g., oral contraceptives) the level of this glycoprotein, thereby changing the amount of anesthetic delivered to the liver for metabolism and thus influencing systemic toxicity. Age-related changes in protein binding of local anesthetics also occur. The neonate is relatively deficient in plasma proteins that bind local anesthetics and thereby is more susceptible to toxicity. Plasma proteins are not the sole determinant of local anesthetic availability. Uptake by the lung also may play an important role in the distribution of amide-linked local anesthetics. Finally, reduced cardiac output slows delivery of the amide compounds to the liver, reducing their metabolism and prolonging their plasma half-lives.

Local Anesthetics and Related Agents

Cocaine
Chemistry
Cocaine, an ester of benzoic acid and methyl ephedrine, occurs in abundance in the leaves of the coca shrub. Egonine is an amino alcohol base closely related to tropane, the amino alcohol in atropine. It has the same fundamental structure as the synthetic local anesthetics (Figure 20–1).

Pharmacological Actions and Preparations
The clinically desired actions of cocaine are the blockade of nerve impulses as a consequence of its local anesthetic properties and local vasoconstriction secondary to inhibition of the NET (see Table 8–5). Toxicity and its potential for abuse have steadily decreased the clinical uses of cocaine. Its high toxicity is due to reduced catecholamine uptake in both the central and peripheral nervous systems and the resulting prolongation of transmitter dwell time in the synaptic cleft. Cocaine’s euphoric properties are due primarily to inhibition of catecholamine uptake, particularly DA, in the CNS. Other local anesthetics do not block the uptake of NE and do not produce the sensitization to catecholamines, vasoconstriction, or mydriasis characteristic of cocaine. Currently, cocaine is used primarily as a local anesthetic of the upper respiratory tract, where its combination of both vasoconstrictor and local anesthetic properties provide anesthesia and shrinkage of the mucosa. Cocaine hydrochloride is provided as a 1%, 4%, or 10% solution for topical application. For most applications, the 1% or 4% preparation is preferred to reduce toxicity. Because of its abuse potential, cocaine is listed as a schedule II controlled substance by the U.S. Drug Enforcement Agency.

Lidocaine
Lidocaine, an aminoethylamide (Figure 20–1), is the prototypical amide local anesthetic.

Pharmacological Actions and Preparations
Lidocaine produces faster, more intense, longer-lasting, and more extensive anesthesia than does an equal concentration of procaine. Lidocaine is an alternative choice for individuals sensitive to ester-type local anesthetics.

A lidocaine transdermal patch is used for relief of pain associated with postherpetic neuralgia. The combination of lidocaine (2.5%) and prilocaine (2.5%) under an occlusive dressing (EMLA, others) is used as an anesthetic prior to venipuncture, skin graft harvesting, and infiltration of anesthetics into genitalia. Lidocaine in combination with tetracaine in a formulation that generates a “peel” is approved for topical local analgesia prior to superficial dermatological procedures such as filler injections and laser-based treatments. Lidocaine in combination with tetracaine is also supplied in a formulation that generates heat on exposure to air, which is used prior to venous access and superficial dermatological procedures such as excision, electrodesiccation, and shave biopsy of skin lesions. The mild warming is intended to increase skin temperature by up to 5°C for the purpose of enhancing delivery of local anesthetic into the skin.

ADME
Lidocaine is absorbed rapidly after parenteral administration and from the GI and respiratory tracts. Although it is effective when used without any vasoconstrictor, epinephrine decreases the rate of absorption, thereby decreasing the probability of toxicity and prolonging the duration of action. In addition to preparations for injection, lidocaine is formulated for topical, ophthalmic, mucosal, and transdermal use.

Lidocaine is dealkylated in the liver by CYPs to monoethylglycine xylidide and glycine xylidide, which can be metabolized further to monoethylglycine and xylidide. Both monoethylglycine xylidide and glycine xylidide retain local anesthetic activity. In humans, about 75% of the xylidide is excreted in the urine as the further metabolite 4-hydroxy-2,6-dimethylaniline (Arthur, 1987).

Toxicity
The side effects of lidocaine seen with increasing dose include drowsiness, tinnitus, dysgeusia, dizziness, and twitching. As the dose increases, seizures, coma, and respiratory depression and arrest will occur. Clinically significant cardiovascular depression usually occurs at serum lidocaine levels that produce marked CNS effects. The metabolites monoethylglycine xylidide and glycine xylidide may contribute to some of these side effects.

Clinical Uses
Lidocaine has a wide range of clinical uses as a local anesthetic; it has utility in almost any application where a local anesthetic of intermediate duration is needed. Lidocaine also is used as an antiarrhythmic agent (Chapter 30).

Bupivacaine
Bupivacaine has a wide range of clinical uses as a local anesthetic; it has utility in almost any application where a local anesthetic of long duration is needed.

Pharmacological Actions and Preparations
Bupivacaine is a widely used amide local anesthetic; its structure is similar to that of lidocaine except that the amine-containing group is a butyl piperidine (Figure 20–1). Bupivacaine is a potent agent capable of producing prolonged anesthesia. Its long duration of action plus its tendency to provide more sensory than motor block has made it a popular drug for providing prolonged analgesia during labor or the postoperative period. By taking advantage of indwelling catheters and continuous infusions, bupivacaine can be used to provide several days of effective analgesia. Recently, a liposomal bupivacaine preparation has been FDA-approved. While safe and effective, its superiority over conventional bupivacaine and its ideal clinical applications remain to be determined (Uskova and O’Connor, 2015).

ADME
Bupivacaine is more slowly absorbed than lidocaine, so plasma levels increase more slowly following a bupivacaine nerve block or epidural. Conversely, bupivacaine levels fall more slowly following cessation of a continuous bupivacaine infusion than would be predicted from single-injection pharmacokinetics. Bupivacaine is primarily metabolized in the liver by CYP3A4 to piperidylxylidine, which is then glucuronidated and excreted.
Toxicity
Bupivacaine is more cardio toxic than equieffective doses of lidocaine. Clinically, this is manifested by severe ventricular arrhythmias and myocardial depression after inadvertent intravascular administration. Although lidocaine and bupivacaine both rapidly block cardiac Na⁺ channels during systole, bupivacaine dissociates much more slowly than lidocaine during diastole, so a significant fraction of Na⁺ channels at physiological heart rates remains blocked with bupivacaine at the end of diastole (Clarkson and Hondeghem, 1985). Thus, the block by bupivacaine is cumulative and substantially more than predicted by its local anesthetic potency. At least a portion of the cardiac toxicity of bupivacaine may be mediated centrally; direct injection of small quantities of bupivacaine into the medulla can produce malignant ventricular arrhythmias (Thomas et al., 1986). Bupivacaine-induced cardiac toxicity can be difficult to treat, and its severity is enhanced by coexisting acidosis, hypercarbia, and hypoxemia, emphasizing the importance of prompt airway control in resuscitation from bupivacaine overdose.

Local Anesthetics Suitable for Injection

The number of synthetic local anesthetics is so large that it is impractical to consider them all here. Some local anesthetic agents are too toxic to be given by injection. Their use is restricted to topical application to the eye (Chapter 69), the mucous membranes, or the skin (Chapter 70). Many local anesthetics are suitable, however, for infiltration or injection to produce nerve block; some of these also are useful for topical application. The discussion below presents the main categories of local anesthetics; agents are listed alphabetically.

Articaine
Articaine is approved in the U.S. for dental and periodontal procedures. Although it is an amide local anesthetic, it also contains an ester, whose hydrolysis terminates its action. Thus, articaine exhibits rapid onset (1–6 min) and duration of action of about 1 h.

Chloroprocaine
Chloroprocaine is a chlorinated derivative of procaine. Its major assets are its rapid onset and short duration of action and its reduced acute toxicity due to rapid metabolism (plasma t₁/₂ ~ 25 sec). Enthusiasm for its use has been tempered by reports of prolonged sensory and motor block after epidural or subarachnoid administration of large doses. This toxicity appears to have been a consequence of low pH and the use of sodium metabisulfite as a preservative in earlier formulations. There are no reports of neurotoxicity with newer preparations of chloroprocaine that contain calcium EDTA as the preservative, although these preparations are not recommended for intrathecal administration. A higher-than-expected incidence of muscular back pain following epidural anesthesia with 2-chloroprocaine has also been reported (Stevens et al., 1993). This back pain is thought to be due to tetany in the paraspinus muscles, which may be a consequence of Ca²⁺ binding by the EDTA included as a preservative; the incidence of back pain appears to be related to the volume of drug injected and its use for skin infiltration.

Mepivacaine
Mepivacaine is an intermediate-acting amino amide with pharmacological properties resembling those of lidocaine. Mepivacaine, however, is more toxic to the neonate and thus is not used in obstetrical anesthesia. The increased toxicity of mepivacaine in the neonate is related to ion trapping of this agent because of the lower pH of neonatal blood and the pH₅₀ of mepivacaine, rather than to its slower metabolism in the neonate. Mepivacaine appears to have a slightly higher therapeutic index in adults than lidocaine. Its onset of action is similar to, and its duration slightly longer (~20%) than, that of lidocaine in the absence of a coadministered vasoconstrictor. Mepivacaine is not effective as a topical anesthetic.

Prilocaine
Prilocaine is an intermediate-acting amino amide. It has a pharmacological profile similar to that of lidocaine. The primary differences are that it causes less vasodilation and thus can be used without a vasoconstrictor; its increased volume of distribution reduces its CNS toxicity, making it suitable for intravenous regional blocks (described further in the chapter).

The use of prilocaine is largely limited to dentistry because the drug is unique among the local anesthetics in its propensity to cause methemoglobinemia. This effect is a consequence of the metabolism of the aromatic ring to o-toluidine. Development of methemoglobinemia is dependent on the total dose administered, usually appearing after a dose of 8 mg/kg. If necessary, it can be treated by the intravenous administration of methylene blue (1–2 mg/kg).

Ropivacaine
The cardiac toxicity of bupivacaine stimulated interest in developing a less-toxic, long-lasting local anesthetic. One result of that search was the development of the amino ethylamide ropivacaine; the S-enantiomer was chosen because it has a lower toxicity than the R-isomer (McClure, 1996). Ropivacaine is slightly less potent than bupivacaine in producing anesthesia. Ropivacaine appears to be suitable for both epidural and regional anesthesia, with a duration of action similar to that of bupivacaine. Interestingly, it seems to be even more motor-sparing than bupivacaine.

Procaine
Procaine is no longer marketed in the U.S. as a single entity. It is an ingredient of some long-acting intramuscular formulations of penicillin.

Tetracaine
Tetracaine is a long-acting amino ester. It is significantly more potent and has a longer duration of action than procaine. Tetracaine may exhibit increased systemic toxicity because it is more slowly metabolized than the other commonly used ester local anesthetics. Currently, it is widely used in spinal anesthesia when a drug of long duration is needed. Tetracaine also is incorporated into several topical anesthetic preparations. With the introduction of bupivacaine, tetracaine is rarely used in peripheral nerve blocks because of the large doses often necessary, its slow onset, and its potential for toxicity.

Agents Used Primarily to Anesthetize Mucous Membranes and Skin

Some agents are useful as topical anesthetic agents on the skin or mucous membranes, although too irritating or too ineffective to be applied to the eye. These preparations are effective in the symptomatic relief of anal and genital pruritus, poison ivy rashes, and numerous other acute and chronic dermatoses. They sometimes are combined with a glucocorticoid or antihistamine and are available in a number of proprietary formulations.

Dibucaine
Dibucaine is a quinoline derivative. Its toxicity resulted in its removal from the U.S. market as an injectable preparation. It retains wide popularity outside the U.S. as a spinal anesthetic. It currently is available as an over-the-counter ointment for cutaneous use.

Dyclonine
Dyclonine hydrochloride is readily absorbed through the skin and mucous membranes. Its onset is rapid; its duration of action is short. Dyclonine is an active ingredient in a number of over-the-counter medications, including sore throat lozenges, a patch for cold sores, and a 0.75% solution.

Pramoxine
Pramoxine hydrochloride is a surface anesthetic agent that is not a benzoate ester. Its distinct chemical structure may help minimize the danger of cross-sensitivity reactions in patients allergic to other local anesthetics. Pramoxine produces satisfactory surface anesthesia and is reasonably well tolerated on the skin and mucous membranes. It is too irritating to be used on the eye or in the nose, but an otic solution containing chloroxylenol is marketed. Many preparations (currently 284 in the U.S.), including creams, lotions, sprays, gel, wipes, and foams, usually containing 1% pramoxine, are available for topical application.

Anesthetics With Low Aqueous Solubility

Some local anesthetics have low aqueous solubility and consequently are absorbed too slowly to cause classical local anesthetic toxicity. These compounds can be applied directly to wounds and ulcerated surfaces, where they remain localized for long periods of time, producing a sustained effect.
anesthetic action. Chemically, they are esters of para-aminobenzoic acid lacking the terminal amino group possessed by the previously described local anesthetics. The most important member of the series is benzocaine (ethyl amino benzoate), which is incorporated into a large number of topical preparations. Benzocaine can cause methemoglobinemia (see the discussion of methemoglobinemia in the section on prilocaine); consequently, dosing recommendations must be followed carefully.

Agents for Ophthalmic Use

Anesthesia of the cornea and conjunctiva can be obtained readily by topical application of local anesthetics. However, most of the local anesthetics that have been described are too irritating for ophthalmological use. The two compounds used most frequently today are proparacaine and tetracaine. In addition to being less irritating during administration, proparacaine has the advantage of bearing little antigenic similarity to the other benzoate local anesthetics. Thus, it sometimes can be used in individuals sensitive to the amino ester local anesthetics.

For use in ophthalmology, these local anesthetics are instilled a single drop at a time. If anesthesia is incomplete, successive drops are applied until satisfactory conditions are obtained. The duration of anesthesia is determined chiefly by the vascularity of the tissue; thus, it is longest in normal cornea and shortest in inflamed conjunctiva. In the latter case, repeated instillations may be necessary to maintain adequate anesthesia. Long-term administration of topical anesthesia to the eye has been associated with retardation of healing, pitting, and sloughing of the corneal epithelium and predisposition of the eye to inadvertent injury. Thus, these drugs should not be prescribed for self-administration. For issues of drug delivery, pharmacokinetics, and toxicity unique to drugs for ophthalmic use, see Chapter 69.

Biological Toxins: Tetrodotoxin and Saxitoxin

The two biological toxins, tetrodotoxin and saxitoxin, block the pore of the Na+ channel. Tetrodotoxin is found in the gonads and other visceral tissues of some fish of the order Tetraodontiformes (to which the Japanese fugu, or puffer fish, belongs); it also occurs in the skin of some newts of the family Salamandridae and of the Costa Rican frog Atelopus. Saxitoxin is elaborated by the dinoflagellates Gonyaulax catenella and G. tamarensis and retained in the tissues of clams and other shellfish that eat these organisms. Given the right conditions of temperature and light, the Gonyaulax may multiply so rapidly as to discolor the ocean, causing the condition known as red tide. Shellfish feeding on Gonyaulax at this time become extremely toxic to humans and are responsible for periodic outbreaks of paralytic shellfish poisoning (Sakai and Swanson, 2014; Stommel and Watters, 2004).

Although these toxins are chemically distinct, they have similar mechanisms of action. Both toxins, in nanomolar concentrations, specifically block the outer mouth of the pore of Na+ channels in the membranes of excitable cells. As a result, the action potential is blocked. The receptor site for these toxins is formed by amino acid residues in the P loop of the Na+ channel a subunit (Figure 22–2) in all four domains (Catterall, 2000; Terlau et al., 1991). Not all Na+ channels are equally sensitive to tetrodotoxin; some Na+ channels in cardiac myocytes and dorsal root ganglion neurons are resistant, and a tetrodotoxin-resistant Na+ channel is expressed when skeletal muscle is denervated. Tetrodotoxin and saxitoxin are exceedingly potent; the minimal lethal dose of each in the mouse is about 8 μg/kg. Both toxins have caused fatal poisoning in humans due to paralysis of the respiratory muscles; therefore, the treatment of severe cases of poisoning requires support of respiration. Blockade of vasomotor nerves, together with a relaxation of vascular smooth muscle, seems to be responsible for the hypotension that is characteristic of tetrodotoxin poisoning. Early gastric lavage and pressor support also are indicated. If the patient survives paralytic shellfish poisoning for 24 h, the prognosis is good.

Clinical Uses of Local Anesthetics

Local anesthesia is the loss of sensation in a body part without the loss of consciousness or the impairment of central control of vital functions. It offers two major advantages over general anesthesia. First, physiological perturbations associated with general anesthesia are avoided. Second, neurophysiological responses to pain and stress can be modified beneficially. However, local anesthetics have the potential to produce deleterious side effects. Proper choice of a local anesthetic and care in its use are the primary determinants in avoiding these problems.

There is a poor relationship between the amount of local anesthetic injected and peak plasma levels in adults. Furthermore, peak plasma levels vary widely depending on the area of injection. They are highest with interpleural or intercostal blocks and lowest with subcutaneous infiltration. Thus, recommended maximum doses serve only as general guidelines. This discussion summarizes the pharmacological and physiological consequences of the use of local anesthetics categorized by method of administration. A more comprehensive discussion of their use and administration is presented in textbooks on regional anesthesia (Cousins et al., 2008).

Topical Anesthesia

Anesthesia of mucous membranes of the nose, mouth, throat, tracheobronchial tree, esophagus, and genitourinary tract can be produced by direct application of aqueous solutions of salts of many local anesthetics or by suspension of the poorly soluble local anesthetics. Tetracaine (2%), lidocaine (2%–10%), and cocaine (1%–4%) typically are used. Cocaine is used only in the nose, nasopharynx, mouth, throat, and ear, where it uniquely produces vasoconstriction as well as anesthesia. The shrinking of mucous membranes without vasoconstriction decreases operative bleeding while improving surgical visualization. Comparable vasoconstriction can be achieved with other local anesthetics by the addition of a low concentration of a vasoconstrictor such as phenylephrine (0.005%). Epinephrine, topically applied, has no significant local effect and does not prolong the duration of action of local anesthetics applied to mucous membranes because of poor penetration. Maximal safe total dosages for topical anesthesia in a healthy 70-kg adult are 300 mg for lidocaine, 150 mg for cocaine, and 50 mg for tetracaine.

Peak anesthetic effect following topical application of cocaine or lidocaine occurs within 2–5 min (3–8 min with tetracaine), and anesthesia lasts for 30–45 min (30–60 min with tetracaine). Anesthesia is entirely superficial; it does not extend to submucosal structures. This technique does not alleviate joint pain or discomfort from subdermal inflammation or injury.

Local anesthetics are absorbed rapidly into the circulation following topical application to mucous membranes or denuded skin. Thus, topical anesthesia always carries the risk of systemic toxic reactions. Systemic toxicity has occurred even following the use of local anesthetics to control discomfort associated with severe diaper rash in infants. Absorption is particularly rapid when local anesthetics are applied to the tracheobronchial tree. Concentrations in blood after instillation of local anesthetics into the airway are nearly the same as those following intravenous injection. Surface anesthetics for the skin and cornea have been described earlier in the chapter.

Eutectic mixtures of local anesthetics lidocaine (2.5%)/prilocaine (2.5%) (EMLA) and lidocaine (7%)/tetracaine (7%) (Pliagis) bridge the gap between topical and infiltration anesthesia. The efficacy of each of these combinations lies in the fact that the mixture has a melting point less than that of either compound alone, existing at room temperature as an oil that can penetrate intact skin. These creams produce anesthesia to a maximum depth of 5 mm and are applied as a cream on intact skin under an occlusive dressing in advance (~30–60 min) of any procedure. These mixtures are effective for procedures involving skin and superficial subcutaneous structures (e.g., venipuncture and skin graft harvesting). Beware: the component local anesthetics will be absorbed into the systemic circulation, potentially producing toxic effects. Guidelines are available to calculate the maximum amount of cream that can be applied and area of skin covered. These mixtures must not be used on mucous membranes or abraded skin, as rapid absorption across these surfaces may result in systemic toxicity.
Local anesthetic is never intentionally injected into the nerve; this would be painful and could cause nerve damage. Instead, the anesthetic agent is deposited as close to the nerve as possible. Thus, the local anesthetic must diffuse from the site of injection into the nerve on which it acts. The rate of diffusion is determined chiefly by the concentration of the drug, its degree of ionization (ionized local anesthetic diffuses more slowly), its hydrophobicity, and the physical characteristics of the tissue surrounding the nerve. Higher concentrations of local anesthetic will provide a more rapid onset of peripheral nerve block. The utility of higher concentrations, however, is limited by systemic toxicity and by direct neural toxicity of concentrated local anesthetic solutions. For a given concentration, local anesthetics with lower $p_K_e$ values tend to have a more rapid onset of action because more drug is uncharged at neutral pH. For example, the onset of action of lidocaine occurs in about 3 min; 35% of lidocaine is in the basic form at pH 7.4. In contrast, the onset of action of bupivacaine requires about 15 min; only 5%–10% of bupivacaine is uncharged at this pH. Increased hydrophobicity might be expected to speed onset by increased penetration into nerve tissue. However, it also will increase binding in tissue lipids. Furthermore, the more hydrophobic local anesthetics also are more potent (and toxic) and thus must be used at lower concentrations. Decreasing the concentration gradient for diffusion and tissue factors also play a role in determining the rate of onset of anesthetic effects. The amount of connective tissue that must be penetrated can be significant in a nerve plexus compared to isolated nerves and can slow or even prevent adequate diffusion of local anesthetic to the nerve fibers.

Duration of nerve block anesthesia depends on the physical characteristics of the local anesthetic used and the presence or absence of vasoconstrictors. Especially important physical characteristics are lipid solubility and protein binding. Local anesthetics can be broadly divided into three categories:

- those with a short (20- to 45-min) duration of action in mixed peripheral nerves, such as procaine;
- those with an intermediate (60- to 120-min) duration of action, such as lidocaine and mepivacaine; and
- those with a long (400- to 450-min) duration of action, such as bupivacaine, ropivacaine, and tetracaine.

Block duration of the intermediate-acting local anesthetics such as lidocaine can be prolonged by the addition of epinephrine (5 μg/mL). The degree of block prolongation in peripheral nerves following the addition of epinephrine appears to be related to the intrinsic vasodilating properties of the local anesthetic and thus is most pronounced with lidocaine.

The types of nerve fibers that are blocked when a local anesthetic is injected about a mixed peripheral nerve depend on the concentration of drug used, nerve fiber size, internodal distance, and frequency and pattern of nerve impulse transmission (see the previous sections on Frequency, Voltage Dependence and Differential Sensitivity of Nerve Fibers). Anatomical factors are similarly important. A mixed peripheral nerve or nerve trunk consists of individual nerves surrounded by an investing epineurium. The vascular supply usually is centrally located. When a local anesthetic is deposited about a peripheral nerve, it diffuses from the outer surface toward the core along a concentration gradient. Consequently, nerves in the outer mantle of the mixed nerve are blocked first. These fibers usually are distributed to more proximal anatomical structures than are those situated near the core of the mixed nerve and often are motor. If the volume and concentration of local anesthetic solution deposited about the nerve are adequate, the local anesthetic eventually will diffuse inward in amounts adequate to block even the most centrally located fibers. Lesser amounts of drug will block only nerves in the mantle and the smaller and more sensitive central fibers. Furthermore, because removal of local anesthetics occurs primarily in the core of a mixed nerve or nerve trunk, where the vascular supply is located, the duration of blockade of centrally located nerves is shorter than that of more peripherally situated fibers.

The choice of local anesthetic and the amount and concentration administered are determined by the nerves and the types of fibers to be blocked, the required duration of anesthesia, and the size and health of the patient. For blocks of 2–4 h, lidocaine (1%–1.5%) can be used in the
amounts recommended previously (see Infiltration Anesthesia). Mepivacaine (up to 7 mg/kg of a 1%–2% solution) provides anesthesia that lasts about as long as that from lidocaine. Bupivacaine (2–3 mg/kg of a 0.25%–0.375% solution) can be used when a longer duration of action is required. Addition of 5 μg/mL epinephrine slows systemic absorption and therefore prolongs duration and lowers the plasma concentration of the intermediate-acting local anesthetics.

Peak plasma concentrations of local anesthetics depend on the amount injected, the physical characteristics of the local anesthetic, whether epinephrine is used, the rate of blood flow to the site of injection, and the surface area exposed to local anesthetic. This is of particular importance in the safe application of nerve block anesthesia because the potential for systemic reactions is related to peak free serum concentrations. For example, peak concentrations of lidocaine in blood following injection of 400 mg without epinephrine for intercostal nerve blocks average 7 μg/mL; the same amount of lidocaine used for block of the brachial plexus results in peak concentrations in blood of about 3 μg/mL (Covino and Vassallo, 1976). Therefore, the amount of local anesthetic that can be injected must be adjusted according to the anatomical site of the nerve(s) to be blocked to minimize untoward effects. Addition of epinephrine can decrease peak plasma concentrations by 20%–30%. Multiple nerve blocks (e.g., intercostal block) or blocks performed in vascular regions require reduction in the amount of anesthetic that can be given safely because the surface area for absorption or the rate of absorption is increased.

**Intravenous Regional Anesthesia (Bier Block)**

The Bier block technique relies on using the vasculature to bring the local anesthetic solution to the nerve trunks and endings. In this technique, an extremity is exsanguinated with an Esmarch (elastic) bandage, and a proximally located tourniquet is inflated to 100–150 mm Hg above the systolic blood pressure. The Esmarch bandage is removed, and the local anesthetic is injected into a previously cannulated vein. Typically, complete anesthesia of the limb ensues within 5–10 min. Pain from the tourniquet and the potential for ischemic nerve injury limit tourniquet inflation to 2 h or less. However, the tourniquet should remain inflated for at least 15–30 min to prevent toxic amounts of local anesthetic from entering the circulation following deflation. Lidocaine, 40–50 mL (0.5 mL/kg in children) of a 0.5% solution without epinephrine, is the drug of choice for this technique. For intravenous regional anesthesia in adults using a 0.5% solution without epinephrine, the dose administered should not exceed 4 mg/kg. A few clinicians prefer prilocaine (0.5%) over lidocaine because of its higher therapeutic index.

The attractiveness of the Bier block lies in its simplicity. Its primary disadvantages are that it can be used only for a few anatomical regions, sensation (pain) returns quickly after tourniquet deflation, and premature release or failure of the tourniquet can produce toxic levels of local anesthetic (e.g., 50 mL of 0.5% lidocaine contains 250 mg of lidocaine). For the last reason and because its longer duration of action offers no advantage, the more cardiotoxic agent bupivacaine is not recommended for this technique. Intravenous regional anesthesia is used most often for surgery of the forearm and hand but can be adapted for the foot and distal leg.

**Spinal Anesthesia**

Spinal anesthesia follows the injection of local anesthetic into the CSF in the lumbar space. For a number of reasons, including the ability to produce anesthesia of a considerable fraction of the body with a dose of local anesthetic that produces negligible plasma levels, spinal anesthesia remains one of the most popular forms of anesthesia. In most adults, the spinal cord terminates above the second lumbar vertebra; between that point and the termination of the thecal sac in the sacrum, the lumbar and sacral roots are bathed in CSF. Thus, in this region there is a relatively large volume of CSF within which to inject drug, thereby minimizing the potential for direct nerve trauma.

The following is a brief discussion of the physiological effects of spinal anesthesia relating to the pharmacology of the local anesthetics. See more specialized texts (Cousins et al., 2008) for additional details.

**Physiological Effects of Spinal Anesthesia**

Most of the physiological side effects of spinal anesthesia are a consequence of the sympathetic blockade produced by local anesthetic block of the sympathetic fibers in the spinal nerve roots. A thorough understanding of these physiological effects is necessary for the safe and successful application of spinal anesthesia. Although some effects may be deleterious and require treatment, others can be beneficial for the patient or can improve operating conditions.

Most sympathetic fibers leave the spinal cord between T1 and L2 (see Figure 8–1). Although local anesthetic is injected below these levels in the lumbar portion of the dural sac, cephalad spread of the local anesthetic occurs with all but the smallest volumes injected. This cephalad spread is of considerable importance in the practice of spinal anesthesia and potentially is under the control of numerous variables, of which patient position and baricity (density of the drug relative to the density of the CSF) are the most important (Greene, 1983). The degree of sympathetic block is related to the height of sensory anesthesia; often, the level of sympathetic blockade is several spinal segments higher because the preganglionic sympathetic fibers are more sensitive to low concentrations of local anesthetic. The effects of sympathetic blockade involve both the actions (now partially unopposed) of the parasympathetic nervous system and the response of the unblocked portion of the sympathetic nervous system. Thus, as the level of sympathetic block ascends, the actions of the parasympathetic nervous system are increasingly dominant, and the compensatory mechanisms of the unblocked sympathetic nervous system are diminished. As most sympathetic fibers leave the cord at T1 or below, few additional effects of sympathetic blockade are seen with cervical levels of spinal anesthesia. The consequences of sympathetic blockade will vary among patients as a function of age, physical conditioning, and disease state. Interestingly, sympathetic blockade during spinal anesthesia appears to be minimal in healthy children.

Clinically, the most important effects of sympathetic blockade during spinal anesthesia are on the cardiovascular system. At all but the lowest levels of spinal blockade, some vasodilatation will occur. Vasodilatation is more marked on the venous than on the arterial side of the circulation, resulting in blood pooling in the venous capacitance vessels. This reduction in circulating blood volume is well tolerated at low levels of spinal anesthesia in healthy patients. With an increasing level of block, this effect becomes more marked, and venous return becomes gravity dependent. If venous return decreases too much, cardiac output and organ perfusion decline precipitously. Venous return can be increased by a modest (10°–15°) head-down tilt or by elevating the legs.

At high levels of spinal blockade, the cardiac accelerator fibers, which exit the spinal cord at T1–T4, will be blocked. This is detrimental in patients dependent on elevated sympathetic tone to maintain cardiac output (e.g., during congestive heart failure or hypovolemia), and it also removes one of the compensatory mechanisms available to maintain organ perfusion during vasodilatation. Thus, as the level of spinal block ascends, the rate of cardiovascular compromise can accelerate if not carefully observed and treated. Sudden asystole also can occur, presumably because of loss of sympathetic innervation in the continued presence of parasympathetic activity at the sinoatrial node (Caplan et al., 1988). In the usual clinical situation, blood pressure serves as a surrogate marker for cardiac output and organ perfusion. Treatment of hypotension usually is warranted when the blood pressure decreases to about 30% of resting values.

Therapy is aimed at maintaining brain and cardiac perfusion and oxygenation. To achieve these goals, administration of oxygen, fluid infusion, manipulation of patient position, and the administration of vasoactive drugs are all options. In practice, patients typically are administered a bolus (500–1000 mL) of fluid prior to the administration of spinal anesthesia in an attempt to prevent some of the deleterious effects of spinal blockade. Because the usual cause of hypotension is decreased venous return, possibly complicated by decreased heart rate, drugs with preferential venoconstrictive and chronotropic properties are preferred. For this reason, ephedrine, 5–10 mg intravenously, often is the drug of choice. In addition to the use of ephedrine to treat deleterious effects of sympathetic blockade, direct-acting a-adrenergic receptor agonists such as...
phenylephrine (Chapter 12) can be administered by either bolus or continuous infusion. A beneficial effect of spinal anesthesia partially mediated by the sympathetic nervous system is on the intestine. Sympathetic fibers originating from T5 to L1 inhibit peristalsis; thus, their blockade produces a small, contracted intestine. This, together with flaccid abdominal musculature, produces excellent operating conditions for some types of bowel surgery. The consequences of spinal anesthesia on the respiratory system are mostly mediated by effects on the skeletal musculature. Paralysis of the intercostal muscles will reduce a patient’s ability to cough and clear secretions, which may produce dyspnea in patients with bronchitis or emphysema. Respiratory arrest during spinal anesthesia seldom occurs due to paralysis of the phrenic nerves or to toxic levels of local anesthetic in the CSF of the fourth ventricle; it is much more likely to be due to medullary ischemia secondary to hypotension.

**Pharmacology**

Currently in the U.S., the drugs most commonly used in spinal anesthesia are lidocaine, tetracaine, and bupivacaine. The choice of local anesthetic is primarily determined by the desired duration of anesthesia. General guidelines are to use lidocaine for short procedures, bupivacaine for intermediate-to-long procedures, and tetracaine for long procedures. As mentioned, the factors contributing to the distribution of local anesthetics in the CSF have received much attention because of their importance in determining the height of block. The most important pharmacological factors include the amount, and possibly the volume, of drug injected and its baricity. The speed of injection of the local anesthesia solution also may affect the height of the block, just as the position of the patient can influence the rate of distribution of the anesthetic agent and the height of blockade achieved (described in the next section). For a given preparation of local anesthetic, administration of increasing amounts leads to a fairly predictable increase in the level of block attained. For example, 100 mg of lidocaine, 20 mg of bupivacaine, or 12 mg of tetracaine usually will result in a T4 sensory block. More complete tables of these relationships can be found in standard anesthesiology texts.

Epinephrine often is added to spinal anesthetics to increase the duration or intensity of block. Epinephrine’s effect on duration of block is dependent on the technique used to measure duration. A commonly used measure of block duration is the length of time it takes for the block to recede by two dermatomes from the maximum height of the block, while a second is the duration of block at some specified level, typically L1. In most studies, addition of 200 μg of epinephrine to tetracaine solutions prolongs the duration of block by both measures. However, addition of epinephrine to lidocaine or bupivacaine does not affect the first measure of duration but does prolong the block at lower levels. In different clinical situations, one or the other measure of anesthesia duration may be more relevant, and this must be kept in mind when deciding whether to add epinephrine to spinal local anesthetics.

The mechanism of action of vasoconstrictors in prolonging spinal anesthesia is uncertain. It has been hypothesized that these agents decrease spinal cord blood flow, decreasing clearance of local anesthetic from the CSF; but this has not been convincingly demonstrated. Epinephrine and other α-adrenergic agonists have been shown to decrease nociceptive transmission in the spinal cord, and studies in genetically modified mice suggested that α₂-adrenergic receptors play a principal role in this response (Stone et al., 1997). Such actions may contribute to the beneficial effects of epinephrine, clonidine, and dexmedetomidine when these agents are added to spinal local anesthetics.

**Drug Baricity and Patient Position**

The baricity of the local anesthetic injected will determine the direction of migration within the dural sac. Hyperbaric solutions will tend to settle in the dependent portions of the sac, while hypobaric solutions will tend to migrate in the opposite direction. Isobaric solutions usually will stay in the vicinity where they were injected, diffusing slowly in all directions. Consideration of the patient position during and after the performance of the block and the choice of a local anesthetic of the appropriate baricity is crucial for a successful block during some surgical procedures. Lidocaine and bupivacaine are marketed in both isobaric and hyperbaric preparations and, if desired, can be diluted with sterile, preservative-free water to make them hypobaric.

**Complications**

Persistent neurological deficits following spinal anesthesia are extremely rare. Thorough evaluation of a suspected deficit should be performed in collaboration with a neurologist. Neurological sequelae can be both immediate and late. Possible causes include introduction of foreign substances (such as disinfectants, ultrasound gel, or talc) into the subarachnoid space, infection, hematoma, or direct mechanical trauma. Aside from drainage of an abscess or hematoma, treatment usually is ineffective; thus, avoidance and careful attention to detail while performing spinal anesthesia are necessary. High concentrations of local anesthetic can cause irreversible block. After administration, local anesthetic solutions are diluted rapidly, quickly reaching nontoxic concentrations. However, there are several reports of transient or longer-lasting neurological deficits following lidocaine spinal anesthesia, particularly with 5% lidocaine HCl (i.e., ~180 mM) in 7.5% glucose (Zaric and Pace, 2009).

Spinal anesthesia sometimes is regarded as contraindicated in patients with preexisting disease of the spinal cord. No experimental evidence exists to support this hypothesis. Nonetheless, it is prudent to avoid spinal anesthesia in patients with progressive diseases of the spinal cord. However, spinal anesthesia may be useful in patients with a fixed, chronic spinal cord injury. A more common sequela following any lumbar puncture, including spinal anesthesia, is a postural headache with classic features. The incidence of headache decreases with increasing age of the patient and decreasing needle diameter. Headache following lumbar puncture must be thoroughly evaluated to exclude serious complications such as meningitis. Treatment usually is conservative, with bed rest and analgesics. If this approach fails, an epidural blood patch with the injection of autologous blood can be performed; this procedure is usually successful in alleviating postdural puncture headaches, although a second blood patch may be necessary. If two epidural blood patches are ineffective in relieving the headache, the diagnosis of postdural puncture headache should be reconsidered. Intravenous caffeine (500 mg as the benzoate salt administered over 4 h) also has been advocated for the treatment of postdural puncture headache; however, the efficacy of caffeine is less than that of a blood patch, and relief usually is transient.

**Evaluation of Spinal Anesthesia**

Spinal anesthesia is a safe and effective technique, especially during surgery involving the lower abdomen, the lower extremities, and the perineum. It often is combined with intravenous medication to provide sedation and amnesia. The physiological perturbations associated with low spinal anesthesia often have less potential harm than those associated with general anesthesia. The same does not apply for high spinal anesthesia. The sympathetic blockade that accompanies levels of spinal anesthesia adequate for mid- or upper abdominal surgery, coupled with the difficulty in achieving visceral analgesia, is such that equally satisfactory and safer operating conditions can be realized by combining the spinal anesthetic with a “light” general anesthetic or by the administration of a general anesthetic and a neuromuscular blocking agent.

**Epidural Anesthesia**

Epidural anesthesia is administered by injecting local anesthetic into the epidural space—the space bounded by the ligamentum flavum posteriorly, the spinal periosteum laterally, and the dura anteriorly. Epidural anesthesia can be performed in the sacral hiatus (caudal anesthesia) or in the lumbar, thoracic, or cervical regions of the spine. Its current popularity arises from the development of catheters that can be placed into the epidural space, allowing either continuous infusions or repeated bolus administration of local anesthetics. The primary site of action of epidurally administered local anesthetics is on the spinal nerve roots. However, epidurally administered local anesthetics also may act on the spinal cord and on the paravertebral nerves.
The selection of drugs available for epidural anesthesia is similar to that for major nerve blocks. As for spinal anesthesia, the choice of drugs to be used during epidural anesthesia is dictated primarily by the duration of anesthesia desired. However, when an epidural catheter is placed, short-acting drugs can be administered repeatedly, providing more control over the duration of block. Bupivacaine, 0.5%–0.75%, is used when a long duration of surgical block is desired. Due to enhanced cardiotoxicity in pregnant patients, the 0.75% solution is not approved for obstetrical use. Lower concentrations—0.25%, 0.125%, or 0.0625%—of bupivacaine, often with 2 μg/mL of fentanyl added, frequently are used to provide analgesia during labor. They also are useful preparations for providing postoperative analgesia in certain clinical situations. Lidocaine 2% is the most frequently used intermediate-acting epidural local anesthetic. Chloroprocaine, 2% or 3%, provides rapid onset and a very short duration of anesthetic action. However, its use in epidural anesthesia has been clouded by controversy regarding its potential ability to cause neurological complications if the drug is accidentally injected into the subarachnoid space (discussed previously). The addition of epinephrine frequently prolongs the duration of action and reduces the toxicity of epidurally administered local anesthetics. Addition of epinephrine also makes inadvertent intravascular injection easier to detect and modifies the effect of sympathetic blockade during epidural anesthesia.

For each anesthetic agent, a relationship exists between the volume of local anesthetic injected epidurally and the segmental level of anesthesia achieved. For example, in 20–40-year-old, healthy, nonpregnant patients, each 1–1.5 mL of 2% lidocaine will give an additional segment of anesthesia. The amount needed decreases with increasing age and during pregnancy and in children. The concentration of local anesthetic used determines the type of nerve fibers blocked. The highest concentrations are used when sympathetic, somatic sensory, and somatic motor blockade are required. Intermediate concentrations allow somatic sensory anesthesia without muscle relaxation. Low concentrations will block only sympathetic fibers. As an example, with bupivacaine these effects might be achieved with concentrations of 0.5%, 0.25%, and 0.0625%, respectively. The total amounts of drug that can be injected with safety at one time are approximately those mentioned in the sections Nerve Block Anesthesia and Infiltration Anesthesia. Performance of epidural anesthesia requires a greater degree of skill than does spinal anesthesia. The technique of epidural anesthesia and the volumes, concentrations, and types of drugs used are described in detail in standard texts on regional anesthesia (Cousins et al., 2008).

A significant difference between epidural and spinal anesthesia is that the dose of local anesthetic used can produce high concentrations in blood following absorption from the epidural space. Peak concentrations of lidocaine in blood following injection of 400 mg (without epinephrine) into the lumbar epidural space average 3–4 μg/mL; peak concentrations of bupivacaine in blood average 1 μg/mL after the lumbar epidural injection of 150 mg. Addition of epinephrine (5 μg/mL) decreases peak plasma concentrations by about 25%. Peak blood concentrations are a function of the total dose of drug administered rather than the concentration or volume of solution following epidural injection (Covino and Vassallo, 1976). The risk of inadvertent intravascular injection is increased in epidural anesthesia, as the epidural space contains a rich venous plexus.

Another major difference between epidural and spinal anesthesia is that there is no zone of differential sympathetic blockade with epidural anesthesia; thus, the level of sympathetic block is close to the level of sensory block. Because epidural anesthesia does not result in the zones of differential sympathetic blockade observed during spinal anesthesia, cardiovascular responses to epidural anesthesia might be expected to be less prominent. In practice, this is not the case; the potential advantage of epidural anesthesia is offset by the cardiovascular responses to the high concentration of anesthetic in blood that occurs during epidural anesthesia. This is most apparent when epinephrine is added to the epidural injection. The resulting concentration of epinephrine in blood is sufficient to produce significant β2 adrenergic receptor–mediated vasodilation. As a consequence, blood pressure decreases, even though cardiac output increases due to the positive inotropic and chronotropic effects of epinephrine (Chapter 12). The result is peripheral hyperperfusion and hypotension. Differences in cardiovascular responses to equal levels of spinal and epidural anesthesia also are observed when a local anesthetic such as lidocaine is used without epinephrine. This may be a consequence of the direct effects of high concentrations of lidocaine on vascular smooth muscle and the heart. The magnitude of the differences in responses to equal sensory levels of spinal and epidural anesthesia varies, however, with the local anesthetic used for the epidural injection (assuming no epinephrine is used). For example, local anesthetics such as bupivacaine, which are highly lipid soluble, are distributed less into the circulation than are less lipid-soluble agents such as lidocaine.

High concentrations of local anesthetics in blood during epidural anesthesia are of particular concern when this technique is used to control pain during labor and delivery. Local anesthetics cross the placenta, enter the fetal circulation, and at high concentrations may cause depression of the neonate. The extent to which they do so is determined by dosage, acid–base status, level of protein binding in both maternal and fetal blood, placental blood flow, and solubility of the agent in fetal tissue. These concerns have been lessened by the trend toward using more dilute solutions of bupivacaine for labor analgesia.

Epidural and Intrathecal Opiate Analgesia

Small quantities of opioid injected intrathecally or epidurally produce segmental analgesia (Yaksh and Rudy, 1976). This observation led to the clinical use of spinal and epidural opioids during surgical procedures and for the relief of postoperative and chronic pain (Cousins and Mather, 1984). As with local anesthesia, analgesia is confined to sensory nerves that enter the spinal cord dorsal horn in the vicinity of the injection. Presynaptic opioid receptors inhibit the release of substance P and other neurotransmitters from primary afferents, while postsynaptic opioid receptors decrease the activity of certain dorsal horn neurons in the spinothalamic tracts (Willcockson et al., 1986; see also Chapters 8 and 20). Because conduction in autonomic, sensory, and motor nerves is not affected by the opioids, blood pressure, motor function, and nonnociceptive sensory perception typically are not influenced by spinal opioids. The volume-evoked micturition reflex is inhibited, as manifested by urinary retention. Other side effects include pruritus, nausea, and vomiting in susceptible individuals. Delayed respiratory depression and sedation, presumably from cephalad spread of opioid within the CSF, occur infrequently with the doses of opioids currently used.

Spinally administered opioids by themselves do not provide satisfactory anesthesia for surgical procedures. Thus, opioids have found the greatest use in the treatment of postoperative and chronic pain, providing excellent analgesia following thoracic, abdominal, pelvic, or lower extremity surgery without the side effects associated with high doses of systemically administered opioids. For postoperative analgesia, spinally administered morphine, 0.2–0.5 mg, usually will provide 8–16 h of analgesia. Placement of an epidural catheter and repeated boluses or an infusion of opioid permits an increased duration of analgesia. Morphine, 2–6 mg every 6 h, commonly is used for bolus injections, while fentanyl, 20–50 μg/h, often combined with bupivacaine at 5–20 mg/h, is used for infusions. For cancer pain, repeated doses of epidural opioids can provide analgesia of several months’ duration. The dose of epidural morphine is far less than the dose of systemically administered morphine that would be required to provide similar analgesia, thus reducing the complications that usually accompany the administration of high doses of systemic opioids, particularly sedation and constipation. Unfortunately, as with systemic opioids, tolerance will develop to the analgesic effects of epidural opioids, but this usually can be managed by increasing the dose.

</table>
Ethanol (CH₃CH₂OH), or beverage alcohol, is a two-carbon alcohol that directly affects many different types of neurochemical systems and signaling cascades and has rewarding and addictive properties. It is the oldest recreational drug and likely contributes to more morbidity, mortality, and public health costs than all illicit drugs combined. The current Diagnostic and Statistical Manual of Mental Disorders (5th ed., DSM-5) integrates alcohol abuse and alcohol dependence into a single disorder called alcohol use disorder (AUD), with mild, moderate, and severe subclassifications (American Psychiatric Association, 2013). This chapter presents an overview of the effects of ethanol on various physiological systems, then focuses on the mechanisms of ethanol's effects in the CNS as the basis for understanding the rewards, disease processes, and treatments for ethanol-related conditions.

Human Consumption of Ethanol: A Brief History and Perspective

The use of alcoholic beverages has been documented as far back as 10,000 BC. By about 3000 BC, the Greeks, Romans, and inhabitants of Babylon were incorporating ethanol into religious festivals, while also using it for pleasure and in medicinal practice. Over the last 2000 years, alcoholic beverages have been identified in most cultures, including pre-Columbian America about AD 200 and the Islamic world in the 8th century.

The dangers of heavy consumption of alcohol have long been recognized by almost all cultures, with most stressing the importance of moderation; yet, problems with ethanol are as ancient as the use of this beverage itself. The increase in ethanol consumption in the 1800s, along with industrialization and the need for a more dependable work force, contributed to the development of more widespread organized efforts to discourage drunkenness, including a constitutional ban on the sale of alcoholic beverages in the U.S. from 1920 to 1933. Today, AUD is one of the most prevalent psychiatric disorders worldwide. In the U.S. among adults 18 years and older, AUD is associated with other substance use and psychiatric disorders; despite its prevalence and comorbidity, AUD often goes untreated (Grant et al., 2015). The highest quantities of ethanol intake per occasion are usually observed in the late teens to early 20s (CDC, 2012). Older adults drink more often but consume fewer total drinks each month (White et al., 2015). In the U.S., the per capita consumption of all alcoholic beverages for persons aged 14 and older is equivalent to 2.3 gallons (8.7 L) of absolute alcohol per year (NIAAA, 2015). Among drinkers, as many as half have experienced an alcohol-related problem, such as missing school or work, alcohol-related amnesia (blackouts), or operating a motor vehicle after consuming alcohol (Schuckit, 2009). Roughly one-third of men (36%) and one-quarter of women (23%) meet criteria for a mild, moderate, or severe AUD in their lifetimes (Grant et al, 2015). The CDC estimated that annually in the U.S. the excessive consumption of ethanol contributes to 10% of deaths of working adults 20–64 years old and to one-third of fatal traffic accidents and cost $249 billion in 2010 (CDC, 2014).

Ethanol Consumption

Compared with other drugs, surprisingly large amounts of ethanol are required for physiological effects. Ethanol is consumed in gram quantities. In contrast, most other drugs with affinities for specific proteins are taken in milligram or microgram doses. The alcohol content of beverages typically ranges from 4% to 6% (volume/volume) for beer, 10% to 15% for wine, and 40% and higher for distilled spirits (the proof of an alcoholic

### Ethanol Absorption and Gastric Metabolism

After oral administration, ethanol is absorbed rapidly into the bloodstream from the stomach and small intestine and distributes into total body water (~0.65 L/kg body weight). Due to high surface area, absorption occurs more rapidly from the small intestine than from the stomach; delays in gastric emptying (e.g., due to the presence of food) slow ethanol absorption. Peak blood levels occur about 30 min after ingestion of ethanol when the stomach is empty. Because of first-pass metabolism by gastric and liver ADH, oral ingestion of ethanol leads to lower BECs than would be obtained if the same dose were administered intravenously. The rate of gastric metabolism of ethanol is lower in women than in men.

### Liver Metabolism

Only small amounts of ethanol are excreted in urine, sweat, and breath. The main enzymes involved in ethanol metabolism are ADH and ALDH, followed by catalase and CYP2E1. CYPs 1A2 and 3A4 may also participate. Ethanol is metabolized primarily by sequential hepatic oxidation, first to acetaldehyde by ADH and then to acetic acid by ALDH (Figure 23–1). Each metabolic step requires NAD⁺; thus, oxidation of 1 mol ethanol (46 g) to 1 mol acetic acid requires 2 mol NAD⁺ (approximately 1.3 kg). This greatly exceeds the supply of NAD⁺ in the liver; thus, the bioavailability of NAD⁺ limits ethanol metabolism to about 8 g/h (10 mL/h, 170 mmol/h) in a 70-kg adult. Ethanol metabolism proceeds via zero-order kinetics at BECs greater than 10 mg% and by first-order kinetics at BECs less than 10 mg%.

In addition to limiting the rate of ethanol metabolism, the large increase in the hepatic NADH:NAD⁺ ratio resulting from ethanol oxidation has profound consequences. The function of NAD⁺-requiring enzymes is impaired, resulting in accumulation of lactate, reduced activity of the tricarboxylic acid cycle, and accumulation of acetyl-CoA (which is produced from ethanol-derived acetic acid; Figure 23–1). The combination of increased NADH and elevated acetyl-CoA supports fatty acid synthesis and the storage and accumulation of triacylglycerides; ketone bodies then accrue, exacerbating lactic acidosis.

Although ADH is responsible for the majority of ethanol metabolism, CYP2E1 accounts for about 10%. This constituent of the microsomal ethanol-oxidizing system can be altered by acute or chronic ethanol consumption. Competition between ethanol and other drugs (e.g., phenytoin and warfarin) that are metabolized by CYP2E1 is observed after acute consumption of ethanol. CYP2E1 is also induced by chronic consumption of ethanol, resulting in increased clearance of its substrates and increased susceptibility to certain toxins (e.g., CCl₄, which CYP2E1 metabolizes and thereby activates to the highly reactive trichloromethyl radical). Ethanol metabolism by the CYP2E1 pathway elevates NADPH and limits the availability of NADPH for the regeneration of reduced glutathione, thereby enhancing oxidative stress.

The mechanisms underlying hepatic disease resulting from heavy ethanol use probably reflect a complex combination of these metabolic factors, CYP2E1 induction (and enhanced activation of toxins and production of H₂O₂ and oxygen radicals), and possibly enhanced release of endotoxin as a consequence of ethanol's effect on gram-negative flora in the GI tract. The often-poor nutritional status of alcoholics (malabsorption and lack of vitamins A and D and thiamine), suppression of immune function, and a variety of other generalized effects likely compound the more direct adverse effects of excessive ethanol consumption. An overview of ethanol metabolism and how it can lead to tissue injury is found in the work of Molina et al. (2014).

### Genetic Variation in Ethanol Metabolism

Genetic variations in metabolic enzymes for ethanol can alter its metabolism and susceptibility to its effects, thus influencing the risk for developing AUD and other pathology. Linkage analyses indicated that genes clustered in the ADH region affect risk for alcohol dependence (Edenberg et al., 2006). SNPs across the ADH region show strong evidence of association in and around the ADH4 gene. In addition, a SNP in the ADH1B gene (ADH1B*2) is found in high frequencies in East Asians that may protect against AUD. This genetic variation produces faster metabolism of ethanol and a transient higher blood level of acetaldehyde, which are associated with a lower risk for heavy drinking and other ethanol-related problems, but a higher risk for esophageal cancer if one drinks. The ADH12*2 polymorphism (see discussion that follows) also leads to an increased incidence of esophageal cancer in those who consume alcohol. Another polymorphism (ADH1B*3) is protective in African Americans and is associated with lower risk of heavy drinking and ethanol-related problems.

Polymorphisms in the ADH12 gene are implicated in the development of AUD (Chen et al., 2014). ALDH2 is the most efficient ADH isozyme in humans for the metabolism of ethanol-derived acetaldehyde. Low levels of acetaldehyde are rewarding and stimulating, while high blood
levels produce adverse reactions such as vomiting, diarrhea, and unstable blood pressure; thus, genetic variation in ALDH activity could affect the rewarding or aversive properties of ethanol. A mutation in the ALDH2 gene (ALDH2*2) produces an enzyme that is incapable of metabolizing ethanol. Approximately 10% of Asians are homozygous for ALDH2*2 and develop severe adverse reactions after the consumption of one drink or less. Similar adverse reactions occur if ethanol is consumed with the ALDH inhibitor disulfiram. Approximately 30%–40% of Asians are heterozygous for ALDH2*2, and these individuals experience facial flushing and enhanced sensitivity to alcohol but do not necessarily report an overall adverse response to the drug. Thus, several polymorphisms may decrease an individual’s risk for developing AUD and other diseases that may be related to the toxic effects of aldehydes. The section Alcohol Use Disorder, Genetics, and Pharmacogenetics provides additional evidence for genetic determinants in AUD.

Methanol
Methanol (CH₃OH), also known as methyl or wood alcohol, is an important industrial reagent and solvent found in products such as paint removers, shellac, and antifreeze. Methanol is added to industrial use ethanol to make it unsafe for human consumption. Ingestion of as little as 10 mg of methanol produces toxicity ranging from blindness to death. The toxic effects of methanol take about 12 or more hours to manifest themselves and are dependent on methanol metabolism to formaldehyde and formic acid (Figure 23–1). Methanol poisoning consists of headache, GI distress, and pain (partially related to pancreatic necrosis), difficulty breathing, restlessness, and blurred vision. The visual disturbances occur from injury to ganglion cells of the retina and the optic nerve by formic acid, which produces inflammation, atrophy, and potential bilateral blindness. Severe metabolic acidosis can develop due to the accumulation of formic acid, and respiratory depression may be severe, resulting in coma or death.

ADME and Treatment of Poisoning
Methanol is rapidly absorbed via oral administration, inhalation, and through the skin, with the last two routes most relevant in industrial settings. Absorption of methanol taken orally typically occurs within 30–60 min. Methanol is metabolized by ADH to formaldehyde, which is then metabolized to formic acid by ALDH. Competition between methanol and ethanol for ADH is the basis for using ethanol to treat methanol poisoning because ethanol slows the rate of formic acid production, lessening the toxicity associated with accidental methanol consumption.

FOMEPIZOLE
Fomepizole (4-methylpyrazole), an ADH inhibitor (Figure 23–1), is also used to treat methanol or ethylene glycol poisoning, applied either alone or in combination with hemodialysis. Plasma levels of 0.8 mg/L are effective in inhibiting ADH. Fomepizole should not be used with ethanol because it prolongs the half-life of ethanol. Treatment of methanol poisoning also consists of treating patients with sodium bicarbonate to combat acidosis.

Effects of Ethanol on Physiological Systems
The Wisdom of Shakespeare
William Shakespeare described the acute pharmacological effects of imbibing ethanol in the Porter scene (act 2, scene 3) of Macbeth. The Porter, awakened from an alcohol-induced sleep by Macduff, explains
three effects of alcohol and then wrestles with a fourth effect that combines the contradictory aspects of soaring overconfidence with physical impairment:

Porter: … and drink, sir, is a great provoker of three things.

Macduff: What three things does drink especially provoke?

Porter: Marry, sir, nose-painting [cutaneous vasodilation], sleep [CNS depression], and urine [a consequence of the inhibition of antidiuretic hormone (vasopressin) secretion, exacerbated by volume loading]. Lecrery, sir, it provokes and unprovokes: it provokes the desire but it takes away the performance. Therefore much drink may be said to be an equivocator with lechery: it makes him and it mars him; it sets him on and it takes him off; it persuades him and dishartens him, makes him stand to and not stand to [the imagination desires what the corpus cavernosum cannot deliver]; in conclusion, equivocates him in a sleep, and, giving him the lie, leaves him.

More recent research has added details to Shakespeare’s enumeration—see the bracketed additions to the Porter’s words in the preceding paragraph and the following sections on organ systems—but the most noticeable consequences of the recreational use of ethanol still are well summarized by the gregarious and garrulous Porter, whose delighted and devilish consequences of the recreational use of ethanol still are well summarized in the bracketed additions to the Porter’s words in the preceding paragraph and the following sections on organ systems—but the most noticeable consequences of the recreational use of ethanol still are well summarized by the gregarious and garrulous Porter, whose delighted and devilish demeanor demonstrates a frequently observed influence of moderate concentrations of ethanol on the CNS. The sections that follow detail ethanol’s effects on physiological systems.

CNS

Ethanol is primarily a CNS depressant. Ingestion of moderate amounts of ethanol, like that of other sedative/hypnotics such as barbiturates and benzodiazepines, can have anxiolytic actions and produce behavioral disinhibition. Individual signs of intoxication vary from expansive and vivacious effects to uncontrolled mood swings and emotional outbursts that may have violent components. With more severe intoxication, CNS function becomes progressively more impaired, ultimately to the point of general anesthesia. Due to respiratory depression, there is little margin between the concentrations yielding the anesthetic and lethal effects of ethanol.

Acute Ethanol Intoxication

Many factors influence the BEC, including body weight, body composition, and the rate of absorption from the GI tract. In women with smaller body size and a lower body water percentage and, consequently, a lower volume of distribution for ethanol, BECs may be about 30%–50% higher than in men for the same quantity consumed.

Signs of intoxication typical of CNS depression are observed in most people after two or three drinks, with the most prominent effects seen at times of peak BEC, about 30–60 min following consumption on an empty stomach. These symptoms include an initial stimulatory effect (perhaps due to inhibition of CNS inhibitory systems), giddiness, muscle relaxation, and impaired judgment. Higher blood levels (−80 mg/dL or −17 mM) are associated with slurred speech, incoordination, unsteady gait, and impaired attention; levels between 80 and 200 mg/dL are associated with more intense mood lability and greater cognitive deficits, potentially accompanied by aggressiveness, and anterograde amnesia (an “alcoholic blackout,” i.e., loss of memory of events that transpired while intoxicated). BECs greater than 200 mg/dL can produce nystagmus and sedation, while levels of 300 mg/dL and higher produce failing vital signs, coma, and death. All of these symptoms are likely to be exacerbated and occur at a lower BEC if ethanol is taken along with other CNS depressants (e.g., benzodiazepines or barbiturates) or with any drug or medication that promotes sedation and incoordination (e.g., antihistamines).

The treatment of acute ethanol intoxication is based on the severity of respiratory and CNS depression. If respiratory depression is not severe, careful observation is the primary treatment. Patients with evidence of respiratory depression should be intubated to protect the airway and to provide ventilatory assistance; stomach lavage can also be considered if absorption is not yet complete. Because it is freely miscible with water, ethanol can be removed from the blood by hemodialysis. The usual protocol involves observing the patient in the emergency room for 4–6 h while the ingested ethanol is metabolized. The symptoms associated with diabetic coma, drug intoxication, cardiovascular accidents, and skull fractures are similar and may be confused with profound alcohol intoxication. Testing for breath odor in a case of suspected intoxication can be misleading because there can be other causes of breath odor similar to that of alcohol (e.g., diabetic ketoacidosis or other metabolic acidosis). Determining blood ethanol levels is necessary to confirm the absence or presence of alcohol intoxication, and diabetes or other underlying conditions should also be considered in patients with positive BECs.

Putative Mechanisms of Ethanol Action in the CNS

Ethanol produces distinct neuroadaptations that depend on acute versus chronic exposure. Ethanol perturbs the balance between excitatory and inhibitory transmission in the brain by either enhancing inhibitory or antagonizing excitatory neurotransmission (Table 23–1). The exact molecular sites responsible for ethanol action in vivo have yet to be resolved, although many ion channels have been implicated, including the ligand-gated NMDA and GABA<sub>A</sub> receptor-operated channels, as well as the large conductance Ca<sup>2+</sup>- and voltage-activated K<sup>+</sup> channel.

Advances in X-ray crystal structures of open and closed states of ion channels combined with structural modeling and site-directed mutagenesis have elucidated selective binding pockets for ethanol in different channel proteins (Howard et al., 2014; Trudell et al., 2014). Ethanol also alters ion channel function indirectly via receptor phosphorylation and trafficking mechanisms (Trudell et al., 2014). Mutant mouse models and genetic association studies in animals and humans further demonstrate a role for ligand-gated ion channels in alcohol dependence. To define the key sites of ethanol action, a combination of functional, structural, behavioral, and genomic approaches will be required.

Addiction, Tolerance, and Dependence

Alcohol use disorder is the chronically relapsing and compulsive use of alcohol, comprising three interacting stages that progressively worsen over time: binge-intoxication, withdrawal-negative affect, and preoccupation-anticipation (“craving”). The neurocircuitry of the basal ganglia is thought to mediate the neurobiological basis of the binge-intoxication stage, including the facilitation of incentive salience, a form of motivational salience associated with reward. The basal ganglia are associated with key functions, including voluntary motor control and procedural learning related to routine behaviors or habits. Release of dopamine and opioid peptides in the ventral striatum (nucleus accumbens) is associated with the reinforcing actions of alcohol (Volkow et al., 2007). Endocannabinoid signaling may also contribute to the motivational and reinforcing properties of ethanol, and ethanol drinking alters...
endocannabinoid levels and cannabinoid receptor 1 expression in brain nuclei associated with addiction pathways (Pava and Woodward, 2012). Alcohol use facilitates incentive salience by imparting motivational properties to previously neutral stimuli. Activation of the ventral striatum leads to recruitment of basal ganglia–globus pallidus–thalamic–cortical loops that engage the dorsal striatum habit formation, hypothesized to be the beginning of compulsive-like responding for drugs.

Tolerance rapidly develops to the rewarding effects of alcohol and is defined as a reduced behavioral or physiological response to the same dose of drug, or the requirement of a higher dose to obtain the same effect (see Chapter 24). The major forms of tolerance are acute and chronic. Acute functional tolerance, also known as the Mellarby effect, occurs within hours of alcohol administration and is due to CNS adaptations to its effects. This is demonstrated by comparing behavioral impairment at the same BECs on the ascending limb of the absorption phase of the BEC–time curve and on the descending limb of the curve, as metabolism reduces the BEC. Behavioral impairment and subjective feelings of intoxication are much greater at a given BEC on the ascending than on the descending limb. Chronic tolerance also develops in the long-term heavy drinker. In contrast to acute tolerance, chronic tolerance has both pharmacodynamic and pharmacokinetic elements, the latter due to induction of alcohol-metabolizing enzymes. In general, the maximum pharmacokinetic tolerance attained would be a doubling of the normal metabolic rate.

Dependence is defined by a withdrawal syndrome observed several hours to days after alcohol consumption is terminated. The symptoms and severity are determined by the amount and duration of drinking and include major motivational changes, sleep disruption, autonomic nervous system (sympathetic) activation, tremors, and, in severe cases, seizures. In addition, two or more days after withdrawal, some individuals experience delirium tremens, characterized by hallucinations, delirium, tachycardia, and a potentially fatal fever. Individuals with AUD also show evidence of negative emotional states during acute withdrawal that persist into protracted abstinence; such states include symptoms related to anxiety, dysphoria, and depression. Persistent depression/anxiety-like symptoms may be relevant in the treatment considerations for AUD.

Two processes are thought to form the neurobiological basis for the withdrawal–negative affect stage: a decrease in functioning in reward systems in the ventral striatum and recruitment of the stress systems in the extended amygdala. As dependence develops, brain stress systems, involving corticotropin–releasing factor, norepinephrine, and dynorphin, are recruited (Koob, 2014), producing a powerful motivation for reengaging in drug seeking.

The preoccupation-anticipation (“craving”) stage involves dysregulation of prefrontal cortex circuits, causing loss of executive control. The completion of complex tasks in the AUD brain may involve two opposing systems. A “go” system, consisting of the anterior cingulate cortex and dorsolateral prefrontal cortex, engages habits via the basal ganglia, while the “stop” system, consisting of the ventrolateral prefrontal cortex and orbitofrontal cortex, inhibits the basal ganglia incentive salience system and the extended amygdala stress system (Koob, 2015). Individuals with AUD present with impairments in decision-making, spatial information, and behavioral inhibition, all of which drive craving. Craving can be divided into “reward” craving (drug seeking induced by drugs or stimuli linked to drugs) and “relief” craving (drug seeking induced by an acute stressor or a state of stress) (Heinz et al., 2003). Thus, deficits in prefrontal cortical control of basal ganglia and extended amygdala function may represent a key mechanism to explain individual differences in the predisposition to and perpetuation of addiction. Residual dysregulation of the neurocircuits mediating incentive salience and stress responsiveness help perpetuate compulsive drug taking and relapse.

Consequences of Ethanol Consumption on CNS Function

The transient CNS effects of heavy ethanol consumption that produce a “hangover”—the next-morning syndrome of headache, thirst, nausea, and fatigue—reflect mechanisms associated with ethanol withdrawal, dehydration, or mild acidosis. Insomnia is a common and persistent problem in AUD, even after weeks of abstinence (Brower, 2015). Insomnia should be treated because it may be a factor contributing to relapse. Ethanol affects respiration and muscle relaxation, and heavy drinking can produce sleep apnea, especially in older alcohol-dependent subjects.

Alcohol use disorder causes shrinkage of the brain due to loss of both white and gray matter, and chronic heavy drinking increases the risk of developing alcoholic dementia. The cognitive deficits and brain atrophy observed soon after a heavy drinking period partially reverse over the subsequent weeks to months following abstinence. Furthermore, alcohol abuse reduces overall brain metabolism, which reverses during detoxification. The magnitude of the hypometabolic state is determined by the number of years of use and the patient’s age.

Wernicke-Korsakoff syndrome consists of two neuropsychiatric disorders: Wernicke encephalopathy, which is largely reversible, and Korsakoff psychosis, which is generally not reversible. These syndromes are now considered a unitary disorder called Wernicke-Korsakoff syndrome that occurs subsequent to inadequate intake of thiamine, likely due to the poor dietary habits of patients with AUD. Thiamine deficiency, alone, can lead to Wernicke-Korsakoff syndrome (Scalzo et al., 2015). Wernicke encephalopathy is characterized by a confusional state, ataxia, abnormal eye movements, blurred vision, double vision, nystagmus, and tremor. It is associated with a prolonged history of heavy drinking and an inadequate nutritional state. The neurological syndrome (ataxia, opthalmoplegia, and nystagmus) can be reversed in its early stages by high doses of thiamine, but the learning and memory impairments respond more slowly and incompletely. Untreated Wernicke encephalopathy leads to death in up to 20% of cases, and 85% of those who survive the encephalopathy go on to develop Korsakoff psychosis, characterized by severe anterograde and retrograde amnesia (Thomson et al., 2012) that is largely irreversible. Wernicke-Korsakoff syndrome is a medical emergency, and early treatment with intravenous thiamine (followed by oral maintenance treatment) is essential to reverse the Wernicke symptoms and prevent progression or reduce the severity of the Korsakoff state.

Neuroendocrine System

Both acute and chronic ethanol exposure alter endocrine regulation via the hypothalamic-pituitary-adrenal, hypothalamic-pituitary-gonadal, and hypothalamic-pituitary-thyroid axes (Molina et al., 2014). Some of the resulting endocrine-related disorders include hypothyroidism, growth retardation, diabetes, as well as hypogonadism and abnormal sexual function, discussed in the next section. Overall, alcohol abuse contributes to an impaired ability to respond to psychological and physical stressors and to maintain homeostasis.

Sexual Function

Many drugs of abuse, including ethanol, have disinhibiting effects that may initially increase libido. Despite the notion that ethanol enhances sexual function, the opposite effect generally prevails, as Shakespeare’s Porter noted. Both acute and chronic ethanol use can lead to impotence in men. Increased BECs lead to decreased sexual arousal, increased ejaculatory latency, and decreased orgasmic pleasure. The incidence of sexual dysfunction may be as high as 70% in those with AUD. In addition, testicular atrophy and decreased fertility may occur. Many females with AUD complain of decreased libido, decreased vaginal lubrication, and menstrual cycle abnormalities. Their ovaries often are small and without follicular development; some data suggest that fertility rates are lower in women with AUD. Gynecocomastia is associated with alcoholic liver disease and is related to an increased estrogen-to-testosterone ratio. Altered levels of reproductive hormones also affect bone metabolism.

Bone

Ethanol interferes with Ca²⁺ and bone metabolism by several processes. Acute ethanol exposure transiently decreases parathyroid hormone, resulting in increased loss of calcium. Chronic ethanol intake can disturb

SECTION II

NEUROPHARMACOLOGY
vitamin D metabolism and decrease Ca\(^{2+}\) absorption. Ethanol is also directly toxic to bone-forming cells and inhibits their activity. AUD is associated with decreased bone mineral density and mass and increased prevalence of osteoporosis, leading to increased risk of fractures. Anabolic hormones, particularly testosterone, are important in regulating bone remodeling and bone mass. The impaired hypothalamo-pituitary-gonadal axis and decreased testosterone levels observed in AUD further contribute to compromised bone health (Molina et al., 2014).

**Body Temperature**

Ingestion of ethanol causes a feeling of warmth due to enhanced cutaneous vasodilatation. Heat is transferred from the body core to the periphery and the core temperature falls due to an effect of ethanol on the central temperature-regulating mechanism in the hypothalamus. Intake of high ethanol doses may lead to pronounced decreases in body temperature, especially in cold ambient temperatures. Alcohol is a major risk factor contributing to deaths from hypothermia.

**Diuresis**

Ethanol inhibits the release of vasopressin (antidiuretic hormone) from the posterior pituitary gland, resulting in enhanced diuresis. Alcohol-dependent individuals in withdrawal exhibit increased vasopressin release and a consequential retention of water, as well as dilutional hyponatremia.

**Cardiovascular System**

There is a complex J-shaped relationship between ethanol consumption and heart disease, a leading cause of death and disability. In general, light-to-moderate ethanol intake decreases risks for coronary artery disease, congestive heart failure, and stroke, whereas high intake increases cardiovascular risk (O’Keefe et al., 2014). Epidemiological studies suggested that gender, ethanol consumption, and drinking patterns affect the association risk for IHD. AUD elevates the risk for IHD, but there is a beneficial association with IHD risk in people who consume less than 30 g per day without episodes of heavy drinking (Roerecke and Rehm, 2014). However, ethanol consumption recommendations from clinicians should remain guarded when judging the overall risk-benefit relationship given the wide range of effects and potential for other ethanol-related problems, presence of other disease states, and the lack of randomized controlled trials on ethanol’s long-term effects. The risk-to-benefit ratio of drinking is also higher in younger individuals.

**Serum Lipoproteins and Cardiovascular Effects**

Epidemiological studies suggest that wine consumption (20–30 g ethanol per day) may confer a cardioprotective effect, resulting in decreased risk of CHD compared with abstainers. In contrast, daily consumption of greater amounts of ethanol leads to an increased incidence of arrhythmias, cardiomyopathy, and hemorrhagic stroke (Movva and Figueredo, 2013). One possible mechanism by which ethanol could reduce the risk of CHD is through its effects on blood lipids. Changes in plasma lipoprotein levels, particularly increases in HDL (see Chapter 33), are linked with the protective effects of ethanol. HDL binds cholesterol and returns it to the liver for elimination or reprocessing, decreasing tissue cholesterol accumulation. Ethanol-induced increases in HDL cholesterol could thus decrease cholesterol accumulation in arterial walls, lessening the risk of infarction. HDL is found as two subfractions, HDL2 and HDL3. Increased levels of HDL2 (and possibly HDL3) are associated with reduced risk of myocardial infarction. Levels of both subfractions increase following ethanol consumption and decrease when consumption ceases. In addition to the antiatherogenic effects of low doses of ethanol, the flavonoids found in red wine (and purple grape juice) may play an additional role by protecting LDL from oxidative damage.

**Hypertension**

Heavy alcohol use can raise diastolic and systolic blood pressure. Consumption of 30 g of ethanol per day is associated with elevations in diastolic–systolic blood pressure, 1.3–2.3 mm Hg in men and 2.1–3.2 mm Hg in women.

**Cardiac Arrhythmias and Cardiomyopathy**

Ethanol-induced arrhythmias may be related to electrolyte abnormalities, prolongation of the QT interval, and hyperadrenergic states. Atrial arrhythmias associated with chronic alcohol use include supraventricular tachycardia, atrial fibrillation, and atrial flutter. Alcoholic cardiomyopathy is a specific disease that is classified among the acquired forms of dilated cardiomyopathy, causing left ventricular dysfunction and dilatation that may or may not be associated with right ventricular dysfunction. In general, studies suggest that consuming more than 80 g of alcohol per day over at least 5 years, in the absence of other causes of cardiomyopathy, constitutes a diagnosis of alcoholic cardiomyopathy (Guzzo-Merello et al., 2014). Women are more sensitive to alcohol than men and develop alcoholic cardiomyopathy at a lower total dose of ethanol. Lowering blood pressure with angiotensin-converting enzyme inhibitors, in particular, may be beneficial in alcoholic cardiomyopathy (Guzzo-Merello et al., 2014).

**Stroke**

A meta-analysis showed that low alcohol intake reduces risk of total stroke, ischemic stroke, and stroke mortality, while heavy intake increases risk of total stroke (Zhang et al., 2014). Clinical studies indicated an increased incidence of hemorrhagic and ischemic stroke in persons who drink more than 40–60 g alcohol per day. Proposed etiological factors include the following:

- Alcohol-induced cardiac arrhythmias and associated thrombus formation
- High blood pressure from chronic alcohol consumption and subsequently cerebral artery degeneration
- Acute increases in systolic blood pressure and alterations in cerebral artery tone
- Head trauma

**Lungs**

As in the heart and other organs, chronic alcohol abuse causes oxidative injury in the lungs. AUD increases risk of acute respiratory distress syndrome and pneumonia (Molina et al., 2014). Alcohol impairs the pulmonary response to injury, infection, and inflammation, resulting in an overall imbalance in the immune response.

**Skeletal Muscle**

Chronic ethanol abuse is associated with decreased muscle mass and strength, even when adjusted for other factors such as age, nicotine use, and chronic illness. Heavy doses of ethanol may irreversibly damage muscle, reflected by a marked increase in the activity of creatine kinase in plasma. Muscle biopsies from heavy drinkers also reveal decreased glycogen stores and reduced pyruvate kinase activity. Approximately 50% of chronic drinkers have skeletal muscle myopathy, which is much greater than the incidence of alcohol cirrhosis (Molina et al., 2014).

**GI Tract and Digestive System**

The GI system mediates ethanol absorption and metabolism and is a target for alcohol-induced pathophysiology, such as impaired esophageal and gastric motility, altered acid secretion, impaired nutrient absorption, and disrupted intestinal barrier function.

**Esophagus**

Alcohol is one of multiple factors associated with esophageal reflux, Barrett esophagus, traumatic rupture of the esophagus, Mallory-Weiss tears, and esophageal cancer. Either tobacco or alcohol use is associated with a 20%–30% increased likelihood of the development of esophageal squamous cell carcinoma; however, the concomitant use of both drugs increases the risk 3-fold. There is little change in esophageal function at low BECs, but at higher BECs peristalsis and lower esophageal sphincter pressure decrease. Patients with chronic reflux esophagitis may respond to proton pump inhibitors, as well as abstinence from alcohol.
**Stomach**

Heavy ethanol use can disrupt the gastric mucosal barrier and cause acute and chronic gastritis. Ethanol concentrations up to 5% stimulate gastric acid secretion, whereas concentrations above 5% have no effect. Alcohol concentrations above 15% inhibit gastric motility and retard emptying of stomach contents. Clinical symptoms of high concentrations of ethanol intake include acute epigastric pain that is relieved with antacids or histamine H₂ receptor antagonists.

**Intestines**

Many individuals with AUD have chronic diarrhea caused by malabsorption in the small intestine. The rectal fissures and pruritus ani that are associated with heavy drinking are likely related to chronic diarrhea. Diarrhea is caused by structural and functional changes in the small intestine; for example, the intestinal mucosa has flattened villi, and digestive enzyme levels often are decreased. These changes are usually reversible after a period of abstinence.

**Pancreas**

Heavy alcohol use is the most common cause of both acute and chronic pancreatitis in the U.S. Acute alcoholic pancreatitis, involving acinar cells, is characterized by the abrupt onset of abdominal pain, nausea, vomiting, and increased levels of serum or urine pancreatic enzymes. Treatment usually involves intravenous fluid replacement (often with nasogastric suction) and opioid pain medication. Similar to alcoholic cirrhosis, chronic pancreatitis results from progressive cellular destruction and fibrosis. Chronic pancreatitis is treated by replacing the resulting endocrine and exocrine deficiencies. Hyperglycemia can develop as a sequela of pancreatic and often requires insulin to control blood sugar levels (see Chapter 47). Pancreatic enzyme capsules containing lipase, amylase, and proteases may be necessary to treat malabsorption (see Chapter 50). The alcohol-induced risk for chronic pancreatitis is increased in smokers, which further exacerbates the risk of pancreatic cancer (Molina et al., 2014).

**Liver**

As the main organ involved in ethanol metabolism, the liver is a primary target for the pathological effects of ethanol. Alcohol misuse is responsible for approximately 50% of liver disease in the U.S. Ethanol produces dose-dependent hepatic injuries that progress from fat accumulation (steatosis) and inflammation to collagen deposition (fibrosis) to loss of liver cells (cirrhosis). The clinical stages of alcoholic liver disease are hepatitis, alcoholic hepatitis, and cirrhosis. Accumulation of fat in the liver is an early event and can occur in normal individuals after the ingestion of relatively small amounts of ethanol. The generation of excess NADH, via metabolism of ethanol and acetaldehyde by ADH and ALDH, inhibits the tricarboxylic acid cycle and the oxidation of fat, leading to steatosis (see Figure 23–1). Steatosis is usually reversible with abstinence.

Hepaticstellate cells play an important role in the development of alcohol-mediated liver fibrosis. Fibrosis, resulting from tissue necrosis and chronic inflammation, is the underlying cause of alcoholic cirrhosis. The histological hallmark of cirrhosis is the formation of intracytoplasmic bodies called Mallory bodies, which may be related to an altered intermediate filament cytoskeleton.

Patients with AUD and alcoholic liver disease show changes in the composition of their intestinal microbiomes, increased intestinal permeability, and increased levels of gut-derived microbial products (Hartmann et al., 2015). Chronic ethanol exposure in animals and humans increases the circulating concentration of LPS, and the severity of hepatic injury correlates with serum levels of LPS. LPS activates TLRs and induces a complex signaling cascade, causing release of reactive oxygen species, chemokines, and pro-inflammatory cytokines.

Treatment of alcoholic hepatitis involves abstinence from alcohol and administration of corticosteroids, but corticosteroids only reduce mortality in the short term (Louvet and Mathurin, 2015). Improved treatment options may come from compounds that target the gut microbiome (see previous discussion), liver inflammation/regeneration, and oxidative stress. Probiotics, antibiotics, anti-inflammatory agents, immunosuppressants, growth factors, and antioxidants are examples of some of the different compounds undergoing clinical trials.

**Cancers**

Ethanol consumption is strongly linked to cancers of the oral cavity, pharynx, larynx, esophagus, colorectum (especially in men), and breast (women); there is also some evidence for an increased risk of liver cancer (Roswall and Weiderpass, 2015). Alcohol dependence plays a role in approximately 3.6% of all cancer cases and a similar percentage of cancer-related deaths (Boffetta et al., 2006). Two- to three-fold increases in cancer susceptibility are seen in individuals who chronically consume 50 g of alcohol per day, and concomitant smoking has a synergistic effect. As mentioned, individuals deficient in ALDH2 activity are particularly vulnerable to esophageal cancer. A notable complication in the treatment of cancer patients with AUD is that ethanol can interfere in the metabolism of some chemotherapeutic agents. The effects of acetaldehyde, a demonstrated carcinogen in animal models, and oxidative stress are widely cited mechanisms for the increased rate of carcinogenesis among individuals with AUD. Evidence also points to a role for aberrant DNA methylation patterns and other epigenetic modifications that control genome activity as mechanisms in alcohol-induced cancer development and progression. Epigenetics refers to processes that affect gene expression without changes in DNA sequence.

**Hematological and Immunological Effects**

Chronic excessive ethanol use is associated with different anemias, including microcytic, macrocytic, normochromic, and sideroblastic anemias, the last of which may respond to vitamin B₁₂ supplementation. Ethanol use also is associated with reversible thrombocytopenia. Ethanol affects granulocytes and lymphocytes, causing leukopenia, alteration of lymphocyte subsets, decreased T-cell mitogenesis, and changes in immunoglobulin production. In some patients with AUD, depressed leukocyte migration into inflamed areas may contribute to poor resistance to some infections (e.g., Klebsiella pneumonia, listeriosis, and tuberculosis). Some effects of ethanol-induced innate immune mechanisms that spread from the periphery to brain are described in the inflammatory sequence of events depicted in the following section.

**Neuroimmune Mechanisms**

The interplay between brain, behavior, and immunity in the etiology and progression of drug abuse is a rapidly developing area of research. Chronic ethanol consumption increases the levels of innate immune signaling molecules that reach the brain, producing alterations in brain physiology and behavior (Mayfield et al., 2013). Binge drinking increases levels of LPS, disrupting tight junctions and contributing to a leaky gut that permits bacteria and endotoxins to enter the circulation and exacerbate liver inflammation (Crews and Vetrano, 2015). This in turn releases pro-inflammatory cytokines that are transported across the blood-brain barrier, eliciting long-lasting neuroimmune responses. Within brain microglia, the actions of innate immune cytokines, activated TLRs, etc., are amplified via complex signaling loops, one of which leads to activation of the transcription factor NF-kB. NF-κB then regulates transcription of pro-inflammatory immune-related genes. Ethanol-induced microglia activation and induction of neuroimmune genes can thus be initiated systemically, through blood-borne molecules, as well as locally in the brain through neuronal-glia signaling. Neuroimmune mechanisms appear to be involved in later stages of heavy drinking and may contribute to neuronal apoptosis. Ethanol-induced neuroimmune activation also occurs in the developing brain, which may be relevant in FASDs (Drew and Kane, 2014).

**Teratogenic Effects: Fetal Alcohol Spectrum Disorders**

Ethanol is the most common teratogen in humans. Children born to mothers who are heavy drinkers display mental deficits and a common pattern of distinct dysmorphology known as FAS. The diagnosis of FAS...
is typically based on the observance of a triad of abnormalities associated with a history of prenatal ethanol exposure (Dorrie et al., 2014):

- A cluster of craniofacial abnormalities
- CNS dysfunction (structural or functional)
- Pre- or postnatal growth deficiencies (weight or height)

Fetal alcohol spectrum disorder is not a diagnostic term used by clinicians but rather an umbrella term that encompasses all of the disabilities caused by prenatal alcohol exposure. For example, children who do not meet all of the criteria for a diagnosis of FAS may show physical or mental deficits consistent with partial phenotypes, including partial FAS, ARND, and ARBD (Dorrie et al., 2014). The incidence of FAS is about 0.5–2 per 1000 live births in the general U.S. population, while the incidence of FAS, ARND, and ARBD combined is at least 1%. Higher rates of FAS occur in African and Native American women. Children of binge-drinking mothers show severe mental and behavioral deficits, likely due to the high peak BECs (Dorrie et al., 2014).

The FAS craniofacial abnormalities associated with maternal drinking in the first trimester consist of microcephaly, shortened palpebral fissures, thin upper lip, smooth philtrum, and epicanthal folds. Magnetic resonance imaging studies demonstrate decreased volumes in the basal ganglia, corpus callosum, cerebrum, and cerebellum that correlate with the facial abnormalities. CNS dysfunction attributed to in utero ethanol exposure consists of hyperactivity; attention and mental deficits; learning disabilities; language, memory, and motor disorders; and psychiatric conditions. FAS is the number one preventable cause of cognitive and attention deficits in the Western world, with afflicted children consistently scoring lower than their peers on a variety of IQ tests. Although the evidence is not conclusive, it has been suggested that even moderate alcohol consumption (28 g per day) in the second trimester of pregnancy is correlated with impaired academic performance of children at age 6. Maternal age also may be a factor: Pregnant women over age 30 who drink alcohol create greater risks to their children than do younger women who consume similar amounts of alcohol. In addition, the intake of high amounts of alcohol, particularly during the first trimester, greatly increases the chances of spontaneous abortion. Current recommendations are to drink no alcohol during pregnancy.

**Clinical Uses of Ethanol**

As mentioned, systemically administered ethanol is confined to the treatment of poisoning by methanol or ethylene glycol. In addition, dehydrated alcohol is injected in close proximity to nerves or sympathetic ganglia to relieve the long-lasting pain related to trigeminal neuralgia, inoperable carcinoma, and other conditions. Epidural, subarachnoid, and lumbar paravertebral injections of ethanol are also administered for inoperable pain. For example, lumbar paravertebral ethanol injections destroy sympathetic ganglia and thereby cause vasodilation and pain relief and promote healing of lesions in patients with vascular disease of the lower extremities.

**Drug Interactions**

Due to synergistic effects, great care must be taken when using sedatives to treat patients who have ingested heavy doses of ethanol or other CNS depressants. Acute ethanol intoxication decreases general anesthetic requirements, and elective surgery should be postponed in intoxicated patients. In contrast, chronic ethanol exposure increases anesthetic requirements largely due to pharmacodynamic cross-tolerance. An additional complication is the use of neuromuscular blockers and sedative/anesthetic agents in patients with AUD presenting with compromised liver function. This is particularly true for patients administered succinylcholine and benzodiazepines.

Pharmacokinetic interactions between ethanol and other drugs also occur. Acute administration of ethanol inhibits the function of enzymes responsible for metabolizing a variety of different drugs, including codeine, morphine, phenytoin, some benzodiazepines, tolbutamide, and warfarin, among others. Because ethanol inhibits CYP2E1, any drug also metabolized by this CYP isozyme will be metabolized at a slower rate in the presence of ethanol. In contrast, the chronic administration of ethanol acts as an enzyme inducer, particularly of CYP2E1, increasing the rate of metabolism of phenytoin, warfarin, propranolol, and benzodiazepines.

**Comorbidity of Alcohol Use Disorder With Other Diseases**

Many systemic diseases are related to chronic alcohol abuse, such as cardiovascular and liver diseases, as well as several types of cancers. AUD appears to increase the risk for diabetes mellitus, hypertension, stroke, osteoporosis, pancreatitis, and many other diseases. In this section, we focus on comorbid mental health conditions that are often present in patients with AUD or other substance use disorders.

**Psychiatric Diseases**

Patients diagnosed with a mood or anxiety disorder are about twice as likely to suffer from a drug abuse disorder and vice versa. In addition, AUD or other drug abuse disorders often occur in people with schizophrenia, leading to increased social and medical problems and complicating the course and treatment of schizophrenia. Patients with AUD and comorbid psychiatric disorders require treatment strategies that address both conditions. Although SSRIs have not been shown to be effective treatments for AUD in patients without a comorbid mental disorder, SSRIs and other antidepressants may decrease intake when AUD and depression co-occur; if alcohol use occurs as a consequence of depression, treating the underlying problem can decrease drinking.

**Post-Traumatic Stress Disorder**

Post-traumatic stress disorder is characterized by extreme hyperarousal and hyperstress responsiveness that contributes in a major way to the classic symptom cluster of reexperiencing, avoidance, and arousal. The prevalence of AUD in individuals with PTSD may be as high as 30% (Ouimette et al., 2005). The study of PTSD neurocircuity has evolved from animal work on fear circuits and shows significant overlap with the symptoms of hyperresponsiveness to stress observed during alcohol withdrawal. One attractive hypothesis of the functional neurocircuitry changes that occur in PTSD is that of a brain-state shift from mild stress, in which the prefrontal cortex inhibits the amygdala, to extreme stress, in which the amygdala dominates (Pitman et al., 2012). Relative cortical dominance conveys resilience, while relative amygdala dominance conveys vulnerability; similar arguments can be made for the resilience and vulnerability to alcoholism, as elaborated by studies of the neurobiology of the withdrawal–negative affect stage of the alcohol addiction cycle.

**Alcohol Use Disorder, Genetics, and Pharmacogenetics**

Similar to other complex trait disorders, the development and progression of AUD is influenced by the interaction of multiple genetic and environmental factors. Environmental and cultural factors include stress, drinking patterns within one’s culture and peer group, availability of alcohol, and attitudes toward drunkenness. These influences contribute to the initial decision to drink and the transition from casual drinking to alcohol-related problems. The heritability of AUD is estimated to be 50%–60%, as judged by family and twin studies. Long-term alcohol abuse and dependence are linked to persistent changes in gene expression (Mayfield et al., 2008).

As discussed previously, SNPs of ADH and ALDH may explain why some populations have a lower risk for AUD. Genetic variants of ADH that exhibit high activity and variants of ALDH that exhibit low activity protect against heavy drinking, likely because ethanol consumption by individuals
expressing these variants results in accumulation of acetaldehyde, producing a variety of unpleasant effects.

Many additional genes modulate responses to ethanol, including variants of the following: µ-opioid receptor (OPRM1), dopamine transporter (SLC6A3), serotonin transporter (SLC6A4), dopamine receptor D2 (DRD2), α1 subunit of the GABA receptor (GABRA2), and α2 subunit of the glycine receptor (GLRA3) (Jonas et al., 2015). Other candidate genes include corticotropin-releasing hormone receptor 1 (CRHHR1) and corticotropin-releasing hormone binding protein (CRHRBP), which are important in brain stress pathways. Ethanol also induces the expression of neuroimmune-related genes, producing increased levels of immune markers detectable in postmortem brains from individuals with AUD (e.g., high-mobility group box 1, interleukin 1β, and TLR4), which may mediate long-term changes in brain function and neurodegeneration. Polymorphisms of genes encoding interleukin 1β and other immune molecules are associated with susceptibility to alcohol dependence (Crews and Vetrano, 2015).

Some of the pharmacotherapies for AUD, discussed in the next section, may be more effective in individuals carrying particular genetic variants. Clinical advances through pharmacogenetic studies of AUD may make the goal of precision medicine possible, but this will require rigorous methodological and statistical analyses. Each individual has unique neurobiological, genetic, and environmental profiles that affect treatment outcome, making individualized strategies not only feasible, but also necessary to move treatment of AUD into mainstream medicine (Litten et al., 2015).

Because AUD involves multifactorial processes with genetic and environmental determinants, as well as neuroadaptations related to disease progression, moving beyond studying the significance of individual candidate genes must include a systems approach to identify the relevant gene and protein networks operating at different stages of the disease. (Gorini et al., 2014).

**Pharmacotherapy of Alcohol Use Disorder**

Currently, three drugs are FDA approved for the treatment of AUD: disulfiram, naltrexone, and acamprosate (Table 23–2). They have reasonable efficacy, with effect sizes similar to those of antidepressant drugs and are associated with relatively low relapse rates. Inhibiting neurotransmitter functioning, the time when the resolve not to drink may be strongest. Sensitization to alcohol may last as long as 14 days after the last ingestion of disulfiram because of the slow rate of restoration of ALDH. Disulfiram or its metabolites can inhibit many enzymes with sulfhydryl groups, producing a wide spectrum of biological effects. Hepatic CYPs are inhibited, thereby interfering with the metabolism of phenytoin, chlor Diazepoxide, barbiturates, warfarin, and other drugs.

**Naltrexone**

Naltrexone, a µ-opioid receptor antagonist, is chemically related to naloxone but has higher oral bioavailability and a longer duration of action when administered orally. It is also approved for treatment of opioid overdose and dependence (see Chapters 18 and 24). There is evidence that naltrexone blocks activation of brain receptors by opioid peptides that are thought to be critical for the rewarding effects of drugs of abuse. Naltrexone reduces craving and decreases relapse to heavy drinking. Meta-analyses indicated that naltrexone is better than placebo, especially in reducing risk of heavy drinking. It is typically administered after detoxification at a dose of 50 mg/d for several months. Adherence to this regimen is important to ensure the therapeutic value of naltrexone but is a problem for some patients. A long-acting depot formulation of naltrexone is available for monthly injection. Naltrexone implants lasting several months are available outside the U.S. The most common side effect of naltrexone is nausea, which subsides if the patient abstains from alcohol. There is some evidence of dysphoria associated with administration of naltrexone, and it is contraindicated in patients with depressive disorders. Doses of naltrexone exceeding 300 mg can cause liver damage; the drug is contraindicated in patients with liver failure or acute hepatitis and should be used only after careful consideration in patients with active liver disease. Naltrexone cannot be given to patients with significant hepatic, cardiac, or renal impairment.

**Disulfiram**

Disulfiram (tetraethylthiuram disulfide), the first drug approved to treat alcohol abuse, is relatively nontoxic when taken in the absence of ethanol. It inhibits ALDH activity and increases the blood acetaldehyde concentration by 5–10 times compared to the level measured when ethanol is administered alone. Disulfiram irreversibly inactivates cytosolic and mitochondrial forms of ALDH to varying degrees. It is unlikely that disulfiram itself is responsible for ALDH inactivation in vivo because several active metabolites of the drug, especially diethylthiocarbamate, behave as suicide-substrate inhibitors of ALDH in vitro. These metabolites reach significant concentrations in plasma following the administration of disulfiram.

Alcohol consumption by individuals previously treated with disulfiram gives rise to marked signs and symptoms of acetaldehyde poisoning. At BECs of 5–10 mg%, mild effects are noted, increasing markedly in severity as the BEC reaches 50 mg%. If the patient attains a BEC of 125–150 mg%, loss of consciousness may occur. Within 5–10 min, the face feels hot and soon afterward becomes flushed and scarlet in appearance. As the vasodilation spreads over the whole body, intense throbbing is felt in the head and neck, and a pulsating headache may develop. Respiratory difficulties, nausea, copious vomiting, sweating, thirst, chest pain, considerable hypotension, orthostatic syncope, marked uneastiness, weakness, vertigo, blurred vision, and confusion are observed. The facial flush is then replaced by pallor, and blood pressure may fall to levels seen in shock. Thus, the use of disulfiram requires careful medical supervision and should only be attempted in motivated patients committed to maintaining abstinence. Patients must learn to avoid disguised forms of alcohol that may be present in sauces, fermented vinegar, cough syrups, and even aftershave lotions. Disulfiram treatment results in poor compliance, possibly because of the adverse effects that result if taken with ethanol.

Disulfiram should not be administered until the patient has abstained from alcohol for at least 12 h. In the initial phase of treatment, a maximal daily dose of 500 mg is given for 1–2 weeks. Maintenance dosage then ranges from 125 to 500 mg daily depending on tolerance to side effects. Unless sedation is prominent, the daily dose should be taken in the morning, the time when the resolve not to drink may be strongest. Sensitization to alcohol may last as long as 14 days after the last ingestion of disulfiram because of the slow rate of restoration of ALDH.

patients taking opioids, but it is used following opioid detoxification for prevention of relapse to opioid dependence.

**Acamprosate**

Acamprosate (N-acetylhomotaurine) may work by blocking a hyperglutamatergic state in the alcoholic brain, but the exact molecular target has remained elusive. It is FDA-approved for the treatment of AUD and is generally well tolerated by patients, with mild diarrhea being the main side effect. Double-blind, placebo-controlled studies demonstrated that acamprosate decreases drinking frequency and reduces relapse drinking in abstinent individuals but may not be effective in those who are currently drinking or misusing other drugs. Meta-analyses of randomized clinical trials showed that acamprosate is associated with reduced relapse in drinking (Jonas et al., 2014). For dosing, see Table 23–2.

**Other Agents**

Baclofen (used in France) has shown positive results for the treatment of AUD in some studies but is not FDA-approved for this use. Three other drugs described next, although not FDA-approved for AUD, are either approved in Europe or may prove useful based on emerging evidence.

- **Nalmefene**, an opioid receptor antagonist structurally similar to naltrexone, is used to treat opioid overdose and may also be used to manage addictive behaviors. It is approved in Europe for as-needed use (18 mg) to reduce heavy drinking. It has several advantages over naltrexone, including longer duration of action, lack of dose-dependent side effect. Double-blind, placebo-controlled studies demonstrated that nalmefene reduces the total amount of alcohol consumed and the number of heavy drinking days in alcohol-dependent patients (van den Brink et al., 2014). Nalmefene was used for opioid overdose in the U.S. but has been discontinued.

- **Gabapentin**, which interacts with the α2δ subunit of neuronal voltage-gated Ca2+ channels, is primarily used to treat epileptic seizures and neuropathic pain. A clinical trial showed that gabapentin (particularly the daily 1800-mg dose) improved rates of abstinence and no heavy drinking days in alcohol-dependent adults, decreased the number of heavy drinking days and number of drinks consumed per week, and decreased the severity of craving, insomnia, and dysphoria (Mason et al., 2014). Additional studies are needed to determine if gabapentin or other agents can be repurposed to treat AUD. For additional information on gabapentin, see Chapter 17.

- **Varenicline**, which is approved for smoking cessation, also reduces alcohol consumption in preclinical and clinical models (Rahman et al., 2014). Varenicline acts as a partial agonist at α3β4, α4β2, and α6β2 subtypes of nAChRs and as a high-efficacy agonist at α7 nAChRs. Given the role of nAChRs in mediating the rewarding properties of ethanol and drugs of abuse, their blockade may offer pharmacological targets for treating patients with AUD who are heavy smokers. For more information on varenicline, consult Chapter 11.

Chapter 24

Drug Use Disorders and Addiction

Charles P. O’Brien

The Confusing Terminology of Drug Use Disorders

ORIGINS OF SUBSTANCE USE DISORDERS
- Agent (Drug) Variables
- Host (User) Variables
- Environmental Variables

PHARMACOLOGICAL PHENOMENA
- Tolerance
- Physical Dependence
- Withdrawal Syndrome

CLINICAL ISSUES: CNS DEPRESSANTS
- Ethanol
- Benzodiazepines

CLINICAL ISSUES: COCAINE AND OTHER PSYCHOSTIMULANTS
- Cocaine
- Amphetamine and Related Agents
- Caffeine
- Cannabinoids (Marijuana)
- Psychedelic Agents

The terminology of drug dependence, abuse, and addiction has long elicited confusion that stems from the fact that repeated use of certain prescribed medications can produce neuroplastic changes resulting in two distinctly abnormal states. The first state is dependence, or “physical” dependence, produced when there is progressive pharmacological adaptation to the drug resulting in tolerance. Tolerance is a normal reaction that is often mistaken for a sign of “addiction.” In the tolerant state, repeating the same dose of a drug produces a smaller effect. If the drug is abruptly stopped, a withdrawal syndrome ensues in which the adaptive responses are now unopposed by the drug. The appearance of withdrawal symptoms is the cardinal sign of “physical” dependence. Addiction, the second abnor-

mal state produced by repeated drug use, occurs in only a minority of those who initiate drug use; addiction leads progressively to compulsive, out-of-control drug use.

Addiction can be considered as a form of maladaptive memory. Addiction begins with the administration of substances (e.g., cocaine) or behaviors (e.g., the thrill of gambling) that directly and intensely acti-
vate brain reward circuits. Activation of these circuits motivates normal behavior, and most humans simply enjoy the experience without being compelled to repeat it. For some (~16% of those who try cocaine), the experience produces strong conditioned associations to environmental cues that signal the availability of the drug or the behavior. The indi-

vidual becomes drawn into compulsive repetition of the experience, focusing on the immediate pleasure despite negative long-term conse-

quences and neglect of important social responsibilities. The distinction between dependence and addiction is important because patients with pain sometimes are deprived of adequate opioid medication by their physician simply because they have shown evidence of tolerance or they exhibit withdrawal symptoms if the analgesic medication is stopped or reduced abruptly. The most recent revision of the classification system (Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition; see American Psychiatric Association, 2013) makes a clear distinction between normal tolerance and a drug use disorder involving compulsive drug seeking.

Origins of Substance Use Disorders

Most of those who initiate use of a drug with addiction potential do not develop a drug use disorder. Many variables operate simultaneously to influence the likelihood that a beginning drug user will lose control and develop an addiction. These variables can be organized into three categories: agent (drug), host (user), and environment (Table 24–1).

Agent (Drug) Variables

Reinforcement refers to the capacity of drugs to produce effects that make the user wish to take them again. The more strongly reinforcing a drug is, the greater is the likelihood that the drug will be abused. Reinforcing properties of drugs are associated with their capacity to increase neuronal activity in brain reward areas (see Chapters 13 and 14). Cocaine, amphetamine, ethanol, opiates, cannabinoids, and nicotine reliably increase extracellular fluid DA levels in the ventral striatum, specifically the nucleus accumbens region. In contrast, drugs that block DA receptors generally produce bad feelings (i.e., dysphoric effects). Despite strong cor-

relative findings, a precise causal relationship between DA and euphoria/dysphoria has not been established, and other findings emphasize addi-
tional roles of 5HT, glutamate, NE, endogenous opioids, and GABA in mediating the reinforcing effects of drugs.

The abuse liability of a drug is enhanced by rapidity of onset. When coca

leaves are chewed, cocaine is absorbed slowly; this produces low cocaine levels in the blood and few, if any, behavioral problems. Crack cocaine, sold illegally and at a low price ($1–$3 per dose in 2016), is alkaloidal cocaine (free base) that can be readily vaporized by heating. Simply inhaling the vapors produces blood levels comparable to those resulting from intravenous cocaine owing to the large surface area for absorption into the pulmonary circulation following inhalation. Thus, inhalation of crack cocaine is much more addictive than chewing, drinking, or sniffing cocaine. The risk for developing addiction among those who try nicotine is about twice that for those who try cocaine (Table 24–2). This does not imply that the pharmacological addiction liability of nicotine is twice that of cocaine. Rather, there are other variables listed in Table 24–1 in the cat-

ergories of Agent (e.g., mode of administration), Host, and Environment that influence the development of addiction.
CHAPTER 24

DRUG USE DISORDERS AND ADDICTION

Abbreviations

AIDS: acquired immune deficiency syndrome
CDC: U.S. Centers for Disease Control and Prevention
CNS: central nervous system
DA: dopamine
DAT: dopamine transporter
DEA: Drug Enforcement Agency
DMT: N, N-dimethyltryptamine
DOM: dimethoxymethylamphetamine
EEG: electroencephalogram
FDA: U.S. Food and Drug Administration
GABA: γ-aminobutyric acid
GI: gastrointestinal
GPCR: G protein–coupled receptor
SHT: serotonin
LSD: lysergic acid diethylamide
MDA: methylenedioxymethamphetamine
MDMA: methylenedioxymethamphetamine
MOR: µ opioid receptor
NE: norepinephrine
NMAD2: N-methyl-D-aspartate
PCP: phencyclidine
Δ-9-THC: Δ-9-tetrahydrocannabinol

TABLE 24–1 ■ MULTIPLE SIMULTANEOUS VARIABLES AFFECTING ONSET AND CONTINUATION OF DRUG ABUSE AND ADDICTION

Agent (drug)
Availability
Cost
Purity/potency
Mode of administration
Chewing (absorption via oral mucous membranes)
Gastrointestinal
Intranasal
Subcutaneous and intramuscular
Intravenous
Inhalation
Speed of onset and termination of effects (pharmacokinetics: combination of agent and host)

Host (user)
Heredity
Innate tolerance
Speed of developing acquired tolerance
Likelihood of experiencing intoxication as pleasure
Metabolism of the drug (nicotine and alcohol data already available)
Psychiatric symptoms
Prior experiences/expectations
Propensity for risk-taking behavior

Environment
Social setting
Community attitudes
Peer influence, role models
Availability of other reinforcers (sources of pleasure or recreation)
Employment or educational opportunities
Conditioned stimuli: environmental cues become associated with drugs after repeated use in the same environment

Notes:

*The ever-used and addiction percentages are those of the general population. The risk of addiction is specific to the drug indicated and refers to the percentage who met criteria for addiction among those who reported having used the agent at least once (i.e., each value in the rightmost column was obtained by expressing the number in the Addiction column as a percentage of the number in the Ever Used column, subject to errors of rounding).

Host (User) Variables

Effects of drugs vary among individuals. Polymorphism of genes that encode enzymes involved in absorption, metabolism, and excretion of a drug and its receptor-mediated responses may contribute to the effects of the drug across the addiction cycle (e.g., euphoria, reinforcement, etc.) (see Chapters 2 through 7). Innate tolerance to alcohol may represent a biological trait that contributes to the development of alcoholism. While innate tolerance increases vulnerability to alcoholism, impaired metabolism may protect against it (see Chapter 23). Similarly, individuals who inherit a gene associated with slow nicotine metabolism may experience unpleasant effects when beginning to smoke and reportedly have a lower probability of becoming nicotine dependent.

Psychiatric disorders constitute another category of host variables. People with anxiety, depression, insomnia, or even shyness may find that certain drugs give them relief. However, the apparent beneficial effects are transient, and repeated use of the drug may lead to tolerance and eventually compulsive, uncontrolled drug use. While psychiatric symptoms are seen commonly in drug abusers presenting for treatment, most of these symptoms begin after the person starts abusing drugs. Thus, drugs of abuse appear to produce more psychiatric symptoms than they relieve.

Environmental Variables

Initiating and continuing illegal drug use is influenced significantly by societal norms and peer pressure.

Pharmacological Phenomena

Tolerance

Tolerance, the most common response to repetitive use of the same drug, can be defined as the reduction in response to the drug after
Conditioned tolerance (Figure 24–1). As the dose of the drug increases, the observed effect of the drug increases. With repeated use of the drug, however, the curve shifts to the right (tolerance). There are many forms of tolerance, likely arising through multiple mechanisms.

Tolerance to some drug effects develops much more rapidly than to other effects of the same drug. For example, tolerance develops rapidly to the euphoria produced by opioids such as heroin, and addicts tend to increase their dose to reexperience that elusive “high.” In contrast, tolerance to the GI effects of opioids develops more slowly. The discrepancy in the speed at which tolerance develops to euphorigenic effects (rapid) and tolerance to effects on vital functions such as respiration and blood pressure (slow) can lead to potentially fatal overdoses.

We can define multiple aspects of tolerance and give examples of some general mechanisms and dosing schedules that contribute:

1. **Innate tolerance** refers to genetically determined lack of sensitivity to a drug the first time that it is experienced.
2. **Acquired tolerance** can be divided into three major types—pharmacokinetic, pharmacodynamic, and learned tolerance—and includes acute, reverse, and cross-tolerance.
   1. **Pharmacokinetic or dispositional tolerance** refers to changes in the distribution or metabolism of a drug after repeated administrations, such that a given dose produces a lower blood concentration than the same dose did on initial exposure. The most common mechanism is an increase in the rate of metabolism of the drug. For example, chronic administration of barbiturates induces hepatic CYPs 1A2, 2C9, 2C19, and 3A4, thereby enhancing the metabolism of drugs that are substrates for these enzymes.
   2. **Pharmacodynamic tolerance** refers to adaptive changes that have taken place within systems affected by the drug so that response to a given concentration of the drug is altered (usually reduced). Examples include drug-induced changes in receptor density or efficiency of receptor coupling to signal transduction pathways (see Chapter 3).
   3. **Learned tolerance** refers to a reduction in the effects of a drug due to compensatory mechanisms that are acquired by past experiences. One type of learned tolerance is called behavioral tolerance. A common example is learning to walk a straight line despite the motor impairment produced by alcohol intoxication. At higher levels of intoxication, behavioral tolerance is overcome; and the behavioral deficits are obvious.
3. **Conditioned tolerance** (situation-specific tolerance) develops when environmental cues or situations consistently are paired with the administration of a drug. When a drug affects homeostatic balance by producing sedation and changes in blood pressure, pulse rate, gut activity, and so on, there is usually a reflexive counteraction or adaptation in the direction of maintaining the status quo. If a drug always is taken in the presence of specific environmental cues (e.g., smell of drug preparation and sight of syringe), these cues begin to predict the effects of the drug, and the adaptations begin to occur, which will prevent the full manifestation of the drug’s effects (i.e., cause tolerance). This mechanism follows classical (Pavlovian) principles of learning and results in drug tolerance under circumstances where the drug is “expected.”

   - **Acute tolerance** refers to rapid tolerance developing with repeated use on a single occasion, such as in a “binge.” For example, repeated doses of cocaine over several hours produce a decrease in response to subsequent doses of cocaine during the binge. This is the opposite of sensitization, observed with an intermittent-dosing schedule.
   - **Sensitization or reverse tolerance** refers to an increase in response with repetition of the same dose of the drug. Sensitization results in a shift to the left of the dose-response curve (see Figure 24–1). Sensitization, in contrast to acute tolerance during a binge, requires a longer interval between doses, usually about 1 day. Sensitization can occur with stimulants such as cocaine or amphetamine.
   - **Cross-tolerance** occurs when repeated use of a drug in a given category confers tolerance not only to that drug but also to other drugs in the same pharmacological category. Understanding cross-tolerance is important in the medical management of persons dependent on a drug.
   - **Detoxification** is a form of treatment of drug dependence that involves giving gradually decreasing doses of the drug to prevent withdrawal symptoms, thereby weaning the patient from the drug of dependence. Detoxification can be accomplished with any medication in the same category as the initial drug of dependence. For example, users of heroin show cross-tolerance to other opioids. Thus, the detoxification of heroin-dependent patients can be accomplished with any medication that activates MORs.

These issues of tolerance, while straightforward, seem to produce a dangerous misunderstanding among self-medicating opioid users. Degrees of tolerance depend on the type of opioid, its half-life, and the route of administration. The typical addicted user is craving the “high” and seems willing to risk overdose by going beyond the safe level. This is especially dangerous when they have progressed to intravenous injection. Accidental overdose has become so common in the U.S. that death in this manner now exceeds the toll for traffic accidents in young people (Rudd et al., 2016).

**Physical Dependence**

Physical dependence is a state that develops as a result of the adaptation (tolerance) produced by a resetting of homeostatic mechanisms in response to repeated drug use. A person in this adapted or physically dependent state requires continued administration of the drug to maintain normal function. If administration of the drug is stopped abruptly, there is another imbalance, and the affected systems must readjust to a new equilibrium without the drug.

**Withdrawal Syndrome**

Withdrawal signs and symptoms occur when drug administration in a physically dependent person is terminated abruptly. The appearance of a withdrawal syndrome when administration of the drug is terminated is the only actual evidence of physical dependence. The type of withdrawal symptoms depends on the pharmacological category of the drug of dependence. Thus, withdrawal of a stimulant causes sedation during withdrawal. Withdrawal of an opioid produces craving for the opioid and physical symptoms, such as nausea, vomiting, and diarrhea, that are the opposite of the opioid’s effects.

Pharmacokinetic variables are of considerable importance in the amplitude and duration of the withdrawal syndrome. Tolerance, physical dependence, and withdrawal are all biological phenomena. They are the natural consequences of drug use and can be produced in experimental animals and in any human being who takes certain substances.
medications repeatedly. These symptoms in themselves do not imply that the individual is involved in drug misuse or addiction. Patients who take medicine for appropriate medical indications and in correct dosages still may show tolerance, physical dependence, and withdrawal symptoms if the drug is stopped abruptly rather than gradually. A physician prescribing a medication that normally produces tolerance must understand the difference between dependence and addiction and be mindful of withdrawal symptoms if the dose is reduced.

Clinical Issues: CNS Depressants

Abuse of multiple drugs in combination is common. Alcohol is so widely available that it is combined with practically all other categories of drugs. Some combinations are reported because of their interactive effects. When confronted with a patient exhibiting signs of overdose or withdrawal, the physician must be aware of these possible combinations because each drug may require a different and specific treatment.

Ethanol

More than 90% of American adults report experience with ethanol (commonly called "alcohol"). Ethanol is classified as a depressant because it produces sedation and sleep. However, the initial effects of alcohol, particularly at lower doses, often are perceived as stimulation owing to a suppression of inhibitory systems (see Chapter 23). Heavy use of ethanol causes development of tolerance and physical dependence sufficient to produce an alcohol withdrawal syndrome when intake is stopped (Table 24–3).

Tolerance, Physical Dependence, and Withdrawal

The symptoms of mild intoxication by alcohol vary among individuals. Some experience motor incoordination and sleepiness. Others initially become stimulated. As the blood level increases, the sedating effects increase, with eventual coma and death occurring at high blood alcohol levels. The innate tolerance to alcohol varies greatly among individuals and is related to family history of alcoholism (Wilhelmsen et al., 2003). Experience with alcohol can produce greater tolerance (acquired tolerance) such that extremely high blood levels (300–400 mg/dL) can be found in alcoholics who do not appear grossly sedated. In these cases, the lethal dose does not increase proportionately to the sedating dose; thus, the margin of safety is decreased.

Heavy consumers of alcohol acquire tolerance and also develop a state of physical dependence. This often leads to drinking in the morning to restore blood alcohol levels diminished during the night. The alcohol withdrawal syndrome generally depends on the size of the average daily dose and usually is "treated" by resumption of alcohol ingestion. Withdrawal symptoms are experienced frequently but usually are not severe or life threatening until they occur in conjunction with other problems, such as infection, trauma, malnutrition, or electrolyte imbalance. In the setting of such complications, the syndrome of delirium tremens becomes likely.

Alcohol addiction produces cross-tolerance to other sedatives, such as benzodiazepines. This tolerance is operative in abstinence alcoholics, but while the alcoholic is drinking, the sedating effects of alcohol add to those of other sedatives. This is particularly true for benzodiazepines, which are relatively safe in overdose when given alone but potentially are lethal in combination with alcohol. The chronic use of alcohol and other sedatives is associated with the development of depression and the risk of suicide. Cognitive deficits have been reported in alcoholics tested while sober. These deficits usually improve with abstinence. More severe recent memory impairment is associated with specific brain damage caused by nutritional deficiencies common in alcoholics (e.g., thiamine deficiency). Medical complications of alcohol abuse and dependence include liver disease, cardiovascular disease, endocrine and GI effects, and malnutrition, in addition to the CNS dysfunctions outlined previously. Ethanol readily crosses the placental barrier, producing the fetal alcohol syndrome, a major cause of mental retardation (see Chapter 23).

Pharmacological Interventions

Detoxification. Although most mild cases of alcohol withdrawal never come to medical attention, severe cases require general evaluation; attention to hydration and electrolytes; vitamins, especially high-dose thiamine; and a sedating medication that has cross-tolerance with alcohol. To block or diminish the symptoms described in Table 24–3, a short-acting benzodiazepine such as oxazepam can be used at a dose of 15–30 mg every 6–8 h according to the stage and severity of withdrawal; some authorities recommend a longer-acting benzodiazepine unless there is demonstrated liver impairment. Anticonvulsants such as carbamazepine have been shown to be effective in alcohol withdrawal, but not as well as benzodiazepines.

Pharmacotherapy. Detoxification is the first step of treatment. Complete abstinence is the objective of long-term treatment, and this is best accomplished by a combination of relapse prevention, anticraving medication, and cognitive behavioral therapy. Disulfiram has been useful in some programs that focus behavioral efforts to promote ingestion of the medication. Disulfiram blocks aldehyde dehydrogenase, resulting in the accumulation of acetaldehyde (Figure 23–1), which produces an unpleasant flushing reaction and nausea when alcohol is ingested. Knowledge that this unpleasant reaction will ensue may help the patient to resist the urge to resume drinking alcohol. However, disulfiram has not proven to be effective in controlled clinical trials because so many patients choose to stop the medication rather than the alcohol.

Naltrexone is an opioid receptor antagonist that blocks the endorphin activation properties of alcohol. Chronic administration of naltrexone decreased the rate of relapse to heavy drinking in randomized clinical trials. The effect varied from strong to weak, but overall, reduction in heavy drinking was a consistent finding (Pettinati et al., 2006).

Naltrexone works best in combination with behavioral treatment programs that encourage adherence to medication and abstinence from alcohol. A depot preparation with a duration of 30 days is now available; it greatly improves medication adherence. Depot naltrexone can also be used in the prevention of relapse in opioid addiction (Lee et al., 2016).

Recent studies of alcohol detoxification have reported that gabapentin can aid in the transition to the abstinent state, possibly by improvement in sleep. Acamprosate, a competitive inhibitor of the NMDA-type glutamate receptor (see Table 23–2), appears to normalize the dysregulated neurotransmission associated with chronic ethanol intake and thereby to attenuate one of the mechanisms that lead to relapse.

Benzodiazepines

Benzodiazepines are used mainly for the treatment of anxiety disorders and insomnia (see Chapters 15 and 17). These agents are widely used, and abuse of prescription benzodiazepines is not uncommon. They may also be combined with alcohol or methadone in the treatment of opioid addiction. The proportion of patients who become tolerant and physically dependent on benzodiazepines increases after several months.

of use, and abrupt reduction of the dose or stopping the medication produces withdrawal symptoms (Table 24–4).

It can be difficult to distinguish benzodiazepine withdrawal symptoms from the reappearance of the anxiety symptoms for which the benzodiazepine was originally prescribed. Some patients may increase their dose over time as tolerance develops to the sedative effects. Antianxiety benefits, however, seem to continue to occur long after tolerance to the sedating effects. Moreover, some patients continue to take the medication for years in appropriate doses according to medical directions and are able to function effectively as long as they take the medication. Patients with a history of alcohol or other drug abuse problems have an increased risk for the development of benzodiazepine abuse and should rarely, if ever, be treated with benzodiazepines on a chronic basis.

**Pharmacological Interventions**

If patients receiving long-term benzodiazepine treatment by prescription wish to stop their medication, the process may take months of gradual dose reduction. Withdrawal symptoms may occur during this outpatient detoxification, but in most cases the symptoms are mild. Patients who have been on low doses of benzodiazepines for years usually have no adverse effects. If anxiety symptoms return, a nonbenzodiazepine such as buspirone may be prescribed. Some authorities recommend transferring the patient to a benzodiazepine with a long t1/2 during detoxification; others recommend the anticonvulsants carbamazepine and phenobarbital. The specific benzodiazepine receptor antagonist flumazenil is useful in the treatment of overdose and in reversing the effects of long-acting benzodiazepines used in anesthesia.

Abusers of high doses of benzodiazepines usually require inpatient detoxification. Frequently, benzodiazepine abuse is part of a combined dependence involving alcohol, opioids, and cocaine. Detoxification can be a complex clinical pharmacological challenge requiring knowledge of the pharmacokinetics of each drug. One approach to complex detoxification is to focus on the CNS depressant drug and temporarily hold the opioid component constant with a low dose of methadone or buprenorphine. A long-acting benzodiazepine such as diazepam or clorazepate or a long-acting barbiturate such as phenobarbital can be used to block the sedative withdrawal symptoms. After detoxification, the prevention of relapse requires a long-term outpatient rehabilitation program similar to the treatment of alcoholism. No specific medications have been found to be useful in the rehabilitation of sedative abusers, but specific psychiatric disorders such as depression or schizophrenia, if present, require appropriate medications.

**Barbiturates**

Abuse problems with barbiturates resemble those seen with benzodiazepines in many ways, and treatment of abuse and addiction to barbiturates should be handled similarly to interventions for the abuse of alcohol and benzodiazepines. Because drugs in this category frequently are prescribed as hypnotics for patients complaining of insomnia, physicians should be aware of the problems that can develop when the hypnotic agent is withdrawn and of possible causes for insomnia that are treatable by other means. Insomnia often is a symptom of an underlying chronic problem, such as depression or respiratory dysfunction. Long-term prescription of sedative medications can change the physiology of sleep and should be avoided. When the sedative is stopped, there is a rebound effect with worsened insomnia. Whether from prescribed hypnotic or self-administered alcohol, medication-induced rebound insomnia requires detoxification by gradual dose reduction. Physicians should not recommend a bedtime drink of alcohol to relieve insomnia; the result is usually disorder sleep.

**Nicotine**

Nicotine and agents for smoking cessation are discussed in Chapter 11. Because nicotine provides the reinforcement for cigarette smoking, the most common cause of preventable death and disease in the U.S., it is arguably the most dangerous dependence-producing drug. Although more than 80% of smokers express a desire to quit, only 35% try to stop each year, and fewer than 5% are successful in unaided attempts to quit.

Tobacco (nicotine) addiction is influenced by multiple variables. Nicotine itself produces reinforcement; users compare nicotine to stimulants such as cocaine or amphetamine, although its effects are of lower magnitude. While there are many casual users of alcohol and cocaine, few individuals who smoke cigarettes smoke a small enough quantity (≤5 cigarettes per day) to avoid dependence. Nicotine is absorbed readily through the skin, mucous membranes, and lungs. The pulmonary route produces discernible CNS effects in as little as 7 sec. Thus, each puff produces some discrete reinforcement. With 10 puffs per cigarette, the 1-pack-per-day smoker reinforces the habit 200 times daily.

In dependent smokers, the urge to smoke correlates with a low blood nicotine level, as though smoking were a means to achieve a certain nicotine level and thus avoid nicotine withdrawal symptoms (Table 24–5). Depressed mood (dysthymic disorder, affective disorder) is associated with nicotine dependence, but it is not known whether depression can predispose one to begin smoking or whether depression develops secondarily during the course of nicotine dependence.

**Pharmacological Interventions**

The nicotine withdrawal syndrome can be alleviated by nicotine replacement therapy (e.g., nicotine inhaler and nasal spray, nicotine gum or lozenge, or nicotine transdermal patch). Different methods of nicotine delivery provide different blood nicotine levels over varying time courses (Figure 24–2). These methods suppress the symptoms of nicotine withdrawal. Although these treatments result in more smokers achieving abstinence, most resume smoking over the ensuing weeks or months. A sustained-release preparation of the antidepressant bupropion (see Chapter 15) improves abstinence rates among smokers and remains a useful option. The cannabinoid CB1 receptor inverse agonist rimonabant improves abstinence rates and reduces the weight gain seen frequently in ex-smokers; unfortunately, rimonabant was found in clinical trials to be linked to depressive and neurologic symptoms and is not approved in the U.S.

Varenicline, a partial agonist at the α4β2 subtype of the nicotinic acetylcholine receptor, reduces cigarette craving and improves long-term abstinence rates. It has high receptor affinity, thus blocking access to nicotine, so if the treated smoker relapses, there is little reward, and abstinence is more likely to be maintained. In one clinical trial, the abstinence rate for

have failed to replicate these reports. See Chapter 11 for the pharmacology of varenicline.

**Opioids**

Opioid drugs are used primarily for the treatment of pain (see Chapter 20). Some of the CNS mechanisms that reduce the perception of pain also produce a state of well-being or euphoria. Thus, opioid drugs also are taken outside medical settings for the purpose of obtaining mood elevation or euphoria. Such use entails a high risk of overdose.

**Death by Overdose**

Heroin is the most frequently abused illicit opioid. Although there is no legal supply of heroin in the U.S., the drug is widely available on the illicit market. The purity of street heroin in the U.S. has increased over the past decade from about 4 mg heroin per 100-mg bag (range 0–8 mg/100 mg; the rest was nonopioid filler such as quinine) to a purity of 45%–75%, with some samples testing as high as 90%. This increase in purity has led to increased levels of physical dependence among heroin addicts. Users who interrupt regular dosing now develop more severe withdrawal symptoms. The more potent supplies can be smoked or administered nasally (snorted), making heroin use accessible to people who would not insert a needle into their veins. The increased potency of heroin has also contributed to more deaths by overdose.

Legal opioids are also abused. During early 21st century, there was increased interest among members of the medical profession in asking patients about pain, giving it a numerical rating, and treating it aggressively with prescription opioids as the agents of choice. In some cases, there was clear overprescribing, especially of extended-release forms of oxycodone, which have been linked to abuse, addiction, and overdose, and FDA approval of another long-acting formulation of oxycodone has provoked controversy (Manchikanti et al., 2014). Opioid overdose has become a common cause of death in many communities, and the latest reports are worrisome, indicating that death from opioid overdose is now about 25,000 annually (DEA, 2015; Rudd et al., 2016). In response, the CDC announced more stringent guidelines for physicians to limit the prescription of opioids for chronic pain (Dowell et al., 2016; see Chapter 20).

**Tolerance, Dependence, and Withdrawal**

Injection of a heroin solution produces a variety of sensations, described as warmth, taste, or high and intense pleasure (“rush”) often compared with sexual orgasm. There are some differences among the opioids in their acute effects; for instance, morphine produces a prominent histamine-releasing effect (causing itching), and meperidine is notable for producing excitation or confusion. Even experienced opioid addicts, however, cannot distinguish between heroin and the common opioid hydromorphone, often used for pain in hospitalized patients. The popularity of heroin may be due to its widespread availability on the illicit market and its rapid onset of effect.

After intravenous injection, the effects begin in less than a minute. Heroin has high lipid solubility, crosses the blood-brain barrier quickly, and is deacetylated to the active metabolites 6-monooacetyl morphine and morphine. After the intense euphoria, which lasts from 45 sec to several minutes, there is a period of sedation and tranquility (“on the nod”) lasting up to an hour. The effects of heroin wear off in 3–5 h, depending on the dose. Experienced users may inject two to four times daily. Thus, the heroin addict is constantly oscillating between being “high” and feeling the sickness of early withdrawal (as depicted in Figure 24–3). This produces many problems in the homeostatic systems regulated at least in part by endogenous opioids.

Based on patient reports, tolerance develops early to the euphoria-producing effects of heroin and other opioids. There also is tolerance to the respiratory depressant, analgesic, sedative, and emetic properties. Heroin users tend to increase their daily dose, depending on their financial resources and the availability of the drug. Overdose is likely to occur when potency of the street sample is unexpectedly high or when the heroin is mixed with a far more potent opioid, such as fentanyl.

Addiction to heroin or other short-acting opioids produces behavioral disruptions and usually becomes incompatible with a productive life. Apart from the behavioral changes and the risk of overdose, chronic use of opioids is relatively nontoxic in and of itself. Nonetheless, the mortality rate for street heroin users is high. Heroin users commonly acquire bacterial infections producing skin abscesses, endocarditis; pulmonary infections, especially tuberculosis; and viral infections producing hepatitis C and AIDS.

Another factor is the use of opioids frequently in combination with other drugs, such as heroin and cocaine (“speedball”). Users report improved euphoria because of the combination, and there is evidence of
an interaction: Cocaine reduces the signs of opiate withdrawal, and heroin may reduce the irritability seen in chronic users of cocaine.

Pharmacological Interventions

Withdrawal and Detoxification. The first stage of treatment addresses physical dependence and consists of detoxification. The opioid withdrawal syndrome (Table 24–6) is unpleasant but not life threatening. It begins within 6–12 h after the last dose of a short-acting opioid and as long as 72–84 h after a long-acting opioid medication. The duration and intensity of the syndrome are related to the clearance of the individual drug. Heroin withdrawal is brief (5–10 days) and intense. Methadone withdrawal is slower in onset and lasts longer.

Opioid withdrawal signs and symptoms can be treated by three different approaches. The first and most commonly used approach consists of transfer to a prescription opioid medication and then gradual dose reduction. It is convenient to change the patient from a short-acting opioid such as heroin to a long-acting one such as methadone. The initial dose of methadone is typically 20–30 mg. The first day’s total dose can be determined by the response and then reduced by 20% per day during the course of detoxification.

A second approach to detoxification involves the use of oral clonidine, an α2 adrenergic agonist that decreases adrenergic neurotransmission from the locus ceruleus. This medication is approved for the treatment of hypertension but is commonly used off label to reduce symptoms of opioid withdrawal. Many of the autonomic symptoms of opioid withdrawal result from the loss of opioid suppression of the locus ceruleus system during the abstinence syndrome. Clonidine can alleviate many of these symptoms but not the generalized aches and opioid craving. Lofexidine, a similar medication, is FDA-approved for use as an opioid withdrawal suppressant. With clonidine and lofexidine, the dose must be titrated according to the stage and severity of withdrawal; postural hypotension is commonly a side effect.

A third method of treating opioid withdrawal involves activation of the endogenous opioid system without medication. The techniques proposed include acupuncture and several methods of CNS activation using transcutaneous electrical stimulation. While attractive theoretically, this method is not yet deemed practical.

Long-Term Management. If patients are simply discharged from the hospital after withdrawal from opioids, there is a high probability of a quick return to compulsive opioid use. Numerous factors influence relapse. The withdrawal syndrome does not end in 5–7 days; a protracted withdrawal syndrome (see Table 24–6) persists for up to 6 months. Physiological measures tend to oscillate as though a new set point were being established; during this phase, outpatient drug-free treatment has a low probability of success, even when the patient has received intensive prior treatment while protected from relapse in a residential program.

The most successful treatment of heroin addiction consists of stabilization on methadone in accordance with state and federal regulations. Patients who relapse repeatedly during drug-free treatment can be transferred directly to methadone without requiring detoxification. The dose of methadone must be sufficient to prevent withdrawal symptoms for at least 24 h.

The introduction of buprenorphine, a partial agonist at the MOR, represents a major change in the treatment of opiate addiction. This drug produces minimal withdrawal symptoms when discontinued and has a low potential for overdose, a long duration of action, and the ability to block heroin effects. Treatment can take place in a qualified physician’s private office rather than in a special center, as required for methadone. When taken sublingually, buprenorphine is active; unfortunately, it also can be dissolved and injected (abused). As a solution to this problem, a buprenorphine-naloxone combination is available. When taken orally (sublingually), the naloxone moiety is not effective, but if the patient abuses the medication by injecting a solution of it, the naloxone will block or diminish the subjective high that could be produced by buprenorphine alone.

Antagonist Treatment. Naltrexone is an antagonist with a high affinity for MOR; it will competitively block the effects of heroin or MOR agonists. Naltrexone will not satisfy craving or relieve protracted withdrawal symptoms, but it can be used after detoxification for patients with high motivation to remain opioid free. Recently, an extended-release depot version of naltrexone has become available (Lee et al., 2016).

Clinical Issues: Cocaine and Other Psychostimulants

Cocaine

In the U.S. in 2014–2015, the number of people aged 12 years or older who are regular users of cocaine (at least monthly) in 2009 was about 1.5 million (FDA, 2016). About 60% of these met the criteria for dependence or abuse defined by the Diagnostic and Statistical Manual of Mental Disorders (American Psychiatric Association, 2013). Cocaine abuse occurs about twice as frequently in men as in women. Not all users become addicts. A key factor in addiction is the widespread availability of relatively inexpensive cocaine in the alkaloidal form (free base, “crack”), suitable for smoking, and in the hydrochloride powder form, suitable for nasal or intravenous use.

The reinforcing effects of cocaine and cocaine analogues correlate best with their effectiveness in inhibiting DAT, the transporter that recovers dopamine from the synapse. This leads to increased DA concentrations at critical brain sites. However, cocaine also blocks both NE and SHT reuptake, and chronic use of cocaine leads to changes in these neurotransmitter systems as well. Cocaine produces a dose-dependent increase in heart rate and blood pressure accompanied by increased arousal, improved performance on tasks of vigilance and alertness, and a sense of self-confidence and well-being. Higher doses produce euphoria, which has a brief duration and often is followed by a desire for more drug. Repeated doses of cocaine may lead to involuntary motor activity, stereotyped behavior, and paranoia. Irritability and increased risk of violence are found among heavy chronic users. The T1/2 of cocaine in plasma is about 50 min, but inhalant (crack) users typically desire more cocaine after 10–30 min.

The major route for cocaine metabolism involves hydrolysis of its two ester groups. Tissue esterases and spontaneous hydrolysis remove the

Caffeine, a mild stimulant, is the most widely used psychoactive drug in the world. It is present in soft drinks, coffee, tea, cocoa, chocolate, and numerous prescription and over-the-counter drugs. Caffeine can inhibit cyclic nucleotide phosphodiesterases, mildly increases NE and DA release, and enhances neural activity in numerous brain areas. Caffeine is absorbed from the digestive tract, is distributed rapidly throughout all tissues, and easily crosses the placental barrier. Caffeine is metabolized largely by CYP1A2, yielding a mean biological half-life of ~5 h, a number that can vary widely. For instance, tobacco smoking reduces it by ~40%; oral contraceptives double it; fluvoxamine increases caffeine's half-life tenfold. Many of caffeine's effects are believed to occur by means of competitive antagonism at adenosine receptors. Adenosine is a neuromodulator (see Chapter 14) that resembles caffeine structurally. The mild sedating effects that occur when adenosine activates particular adenosine receptor subtypes can be antagonized by caffeine. Tolerance occurs rapidly to the stimulating effects of caffeine. Thus, a mild withdrawal syndrome has been produced in controlled studies by abruptly discontinuing the intake of as little as one to two cups of coffee per day. Caffeine withdrawal consists of feelings of fatigue and sedation. With higher doses, headaches and nausea have been reported during withdrawal; vomiting is rare.

**Cannabinoids (Marijuana)**

The cannabis plant has been cultivated for centuries for its presumed medicinal and psychoactive properties. The smoke from burning cannabis contains many chemicals, including 61 different cannabinoids that have been identified. One of these, A9-THC, produces most of the characteristic pharmacological effects of smoked marijuana. In the U.S., marijuana use remains prohibited by federal law, but it is approved in thirteen states as medicine and in eight states for recreational purposes. This is leading to increased marijuana use and a greater number of marijuana-associated auto accidents. The issues of whether and how to control the use of marijuana have not been resolved. In addition, the potencies of available botanical forms have generally not been standardized, and the dangers inherent in inhaling a smoke replete with organic molecules have not been defined for marijuana smoke.

**Amphetamine and Related Agents**

Subjective effects similar to those of cocaine are produced by amphetamine, dextroamphetamine, methamphetamine, phenmetrazine, methylphenidate, and diethylpropion. Amphetamines increase synaptic DA, NE, and 5HT primarily by stimulating presynaptic release of stored neurotransmitter (see Chapter 8). Intravenous or smoked methamphetamine produces an abuse/dependence syndrome similar to that of cocaine, although clinical deterioration may progress more rapidly. Methamphetamine addiction has become a major public health problem in the U.S. Behavioral and medical treatments for methamphetamine addiction are similar to those used for cocaine.

**Pharmacological Interventions**

Because cocaine withdrawal is generally mild, treatment of withdrawal symptoms usually is not required. The major problem in treatment is not detoxification but helping the patient to resist the urge to resume compulsive cocaine use. Rehabilitation programs involving individual and group psychotherapy based on the principles of Alcoholics Anonymous and behavioral treatments based on reinforcing cocaine-free urine tests result in significant improvement in the majority of cocaine users. Animal models suggest that enhancing GABAergic inhibition can reduce reinstatement of cocaine self-administration, and a controlled clinical trial of topiramate showed a significant reduction in cocaine use. Topiramate also reduced the relapse rate in alcoholics, prompting current studies in patients dually dependent on cocaine and alcohol. Baclofen, a GABA<sub>B</sub> agonist, was found in a single-site trial to reduce relapse in cocaine addicts but was not effective in a multisite trial. Modafinil is currently being tested in clinical trials of cocaine, methamphetamine, alcohol, and other substance abuse disorders. A mild stimulant approved for treating narcolepsy, modafinil has had several positive clinical trials for use in cocaine withdrawal (Morgan et al., 2016). The medication reduces the euphoria produced by cocaine and relieves cocaine withdrawal symptoms. It remains under investigation for this purpose.

**Tolerance, Dependence, and Withdrawal**

In intermittent users of cocaine, the euphoric effect typically is not subject to sensitization. On the contrary, most experienced users become desensitized and, over time, require more cocaine to obtain euphoria (i.e., tolerance develops). Because cocaine typically is used intermittently, even heavy users go through frequent periods of withdrawal or "crash." The symptoms of withdrawal seen in users admitted to hospitals are listed in Table 24–7. Careful studies of cocaine users during withdrawal showed gradual diminution of these symptoms over 1–3 weeks. Residual depression, often seen after cocaine withdrawal, should be treated with antidepressant agents if it persists (see Chapter 15).

The human cannabinoid endogenous ligand/receptor/signaling systems are described in Chapter 14 (see Figure 14–17). This system is stimulated by exogenous Δ9-THC. The pharmacological effects of Δ9-THC vary with the dose, route of administration, experience of the user, vulnerability to psychoactive effects, and setting of use. Intoxication with marijuana produces changes in mood, perception, and motivation, but the effects most frequently sought are a “high” and a “mellowing out.” Effects vary with dose, but typically last about 2 h. During the high, cognitive functions, perception, reaction time, learning, and memory are impaired. Coordination and tracking behavior may be impaired for several hours beyond the perception of the high. Marijuana also produces complex behavioral changes such as giddiness and increased hunger. Unpleasant reactions such as panic or hallucinations and even acute psychosis may occur. These reactions are seen commonly with higher doses and with oral ingestion rather than smoked marijuana. Numerous clinical reports suggest that marijuana use may precipitate a recurrence of psychosis in people with a history of schizophrenia. One of the most controversial putative effects of marijuana is the production of an “amotivational syndrome.” This syndrome is not an official diagnosis but has been used to describe young people who drop out of social activities and show little interest in school, work, or other goal-directed activity. At the cellular level, there is no evidence that marijuana damages brain cells or produces any permanent functional changes. There is evidence that the CB1 receptor, a highly abundant GPCR in the mammalian brain, can deliver neuroprotective signals in animal models of striatal damage (Blázquez et al., 2015).

Marijuana has medicinal effects, including antiepileptic properties that relieve side effects of anticancer chemotherapy. It also has muscle-relaxing effects, anticonvulsant properties, and the capacity to reduce the elevated intraocular pressure of glaucoma. These medical benefits come at the cost of the psychoactive effects that often impair normal activities. Dronabinol is an approved formulation of Δ9-THC (see Chapters 14 and 50).

**Tolerance, Dependence, and Withdrawal**

Tolerance to most of the effects of marijuana can develop rapidly after only a few doses, but also disappears rapidly. Withdrawal symptoms are not seen in clinical populations. Human subjects develop a withdrawal syndrome when they receive regular oral doses of the agent (Table 24–8). This syndrome, however, is only seen clinically in persons who use marijuana on a daily basis and then suddenly stop. Marijuana abuse and addiction have no specific treatments. Heavy users may suffer from accompanied depression and thus may respond to antidepressant medication.

**Psychedelic Agents**

There are two main categories of psychedelic compounds, indoleamines and phenethylamines. The indoleamine hallucinogens include LSD, DMT, and psilocybin. The phenethylamines include mescaline, DOM, MDA, and MDMA. Both groups have a relatively high affinity for 5HT receptors (see Chapter 13), but they differ in their affinity for other subtypes of 5HT receptors. There is a good correlation between the relative affinity of these compounds for 5HT receptors and their potency as hallucinogens in humans. LSD interacts with most brain 5HT receptors as an agonist/partial agonist and elicits sensory distortions (especially visual) and hallucinations at doses as low as 1 μg/kg. Current hypotheses of the mechanism of action of LSD and other hallucinogens focus on 5HT1 receptor–mediated disruption of thalamic gating with sensory overload of the cortex (Nichols, 2016).

**LSD**

LSD is the most potent hallucinogenic drug, more than 3000 times more potent than mescaline. LSD is sold on the illicit market in a variety of forms. A popular contemporary system involves postage stamp–size papers impregnated with varying doses of LSD (50–300 μg or more). The effects of hallucinogenic drugs are variable, even in the same individual on different occasions. LSD is absorbed rapidly after oral administration, with effects beginning at 40–60 min, peaking at 2–4 h, and gradually returning to baseline over 6–8 h. At a dose of 100 μg, LSD produces perceptual distortions and sometimes hallucinations; mood changes, including elation, paranoia, or depression; intense arousal; and sometimes a feeling of panic. Signs of LSD ingestion include pupillary dilatation, increased blood pressure and pulse, flushing, salivation, lacrimation, and hyperreflexia. Visual effects are prominent. Colors seem more intense, and shapes may appear altered. The subject may focus attention on unusual items, such as the pattern of hairs on the back of the hand.

A “bad trip” usually consists of severe anxiety, although at times it can be marked by intense depression and suicidal thoughts. Visual disturbances usually are prominent. There are no documented toxic fatalities from LSD use, but fatal accidents and suicides have occurred during or shortly after intoxication. Prolonged psychotic reactions lasting 2 days or more may occur after the ingestion of a hallucinogen. Schizophrenic episodes may be precipitated in susceptible individuals, and there is some evidence that chronic use of these drugs is associated with the development of persistent psychotic disorders. Claims about the potential of psychedelic drugs for enhancing psychotherapy and for treating addictions and other mental disorders are not supported by controlled studies; there is no generally accepted indication for these drugs as medications.

**Tolerance, Physical Dependence, and Withdrawal.** Frequent, repeated use of psychedelic drugs is unusual; thus, tolerance is not commonly seen. Tolerance does develop to the behavioral effects of LSD after three or four daily doses, but no withdrawal syndrome has been observed.

**Pharmacological Intervention.** Because of the unpredictability of psychedelic drug effects, any use carries some risk. Users may require medical attention because of bad trips. Severe agitation may respond to diazepam (20 mg orally). “Talking down” by reassurance also is effective and is the management of first choice. Antipsychotic medications (see Chapter 16) may intensify the experience and thus are contraindicated. A particularly troubling aftereffect of LSD and similar drugs is the occasional occurrence of episodic visual disturbances. These originally were called “flashbacks” and resembled the experiences of prior LSD trips. Flashbacks belong to an official diagnostic category called the hallucinogen persisting perception disorder. The symptoms include false fleeting perceptions in the peripheral fields, flashes of color, geometric pseudohallucinations, and positive afterimages. The visual disorder appears stable in half the cases and represents an apparently permanent alteration of the visual system. Precipitants include stress, fatigue, emergence into a dark environment, marijuana, antipsychotic agents, and anxiety states.

**MDMA (“Ecstasy”) and MDA**

MDMA and MDA are phenylethylamines that have stimulant as well as psychedelic effects. Acute effects are dose dependent and include feelings of energy, altered sense of time, and pleasant sensory experiences with enhanced perception. Negative effects include tachycardia, dry mouth, jaw clenching, and muscle aches. At higher doses, visual hallucinations, agitation, hyperthermia, and panic attacks have been reported. A typical oral dose is one or two 100-mg tablets, producing effects lasting 3–6 h, although dosage and potency of street samples are variable (~100 mg of active drug per tablet).

**Phencyclidine**

PCP was developed originally as an anesthetic in the 1950s and later was abandoned because of a high frequency of postoperative delirium with hallucinations. It was classified as a dissociative anesthetic because, in the anesthetized state, the patient remains conscious with staring gaze, flat facies, and rigid muscles. PCP became a drug of abuse in the 1970s, first in an oral form and then in a smoked version enabling a better regulation of the dose.
As little as 50 μg/kg produces emotional withdrawal, concrete thinking, and bizarre responses to projective testing. Catatonic posturing also is produced and resembles that of schizophrenia. Abusers taking higher doses may appear to be reacting to hallucinations and may exhibit hostile or assaultive behavior. Anesthetic effects increase with dosage; stupor or coma may occur with muscular rigidity, rhabdomyolysis, and hyperthermia. Intoxicated patients in the emergency room may progress from aggressive behavior to coma, with elevated blood pressure and enlarged, nonreactive pupils. PCP binds with high affinity to sites located in the cortex and limbic structures, blocking NMDA-type glutamate receptors (see Table 14–2 and Figures 14–12 and 14–13). There is evidence that NMDA receptors are involved in ischemic neuronal death caused by high levels of excitatory amino acids; as a result, there is interest in PCP analogues of excitatory amino acids; as a result, there is interest in PCP analogues that block NMDA receptors but with fewer psychoactive effects. Both PCP and ketamine (“special K”), another “club drug,” produce similar effects by altering the distribution of the neurotransmitter glutamate.

**Medical Intervention.** Overdose must be treated by life support; there is no antagonist of PCP effects and no proven way to enhance excretion, although acidification of the urine has been proposed. PCP coma can last 7–10 days. The agitated or psychotic state produced by PCP can be treated with diazepam. Prolonged psychotic behavior requires antipsychotic medication. Because of the anticholinergic activity of PCP, antipsychotic agents with significant anticholinergic effects such as chlorpromazine should be avoided.

Drugs Affecting Renal Excretory Function

Edwin K. Jackson

PART I: RENAL PHYSIOLOGY AND DIURETIC DRUG ACTION
- Renal Anatomy and Physiology
- Principles of Diuretic Action
- Inhibitors of Carbonic Anhydrase
- Osmotic Diuretics
- Inhibitors of Na⁺-K⁺-2Cl⁻ Symport: Loop Diuretics, High-Ceiling Diuretics
- Inhibitors of Na⁺-Cl⁻ Symport: Thiazide-Type and Thiazide-Like Diuretics
- Inhibitors of Renal Epithelial Na⁺ Channels: K⁺-Sparing Diuretics
- Antagonists of Mineralocorticoid Receptors: Aldosterone Antagonists, K⁺-Sparing Diuretics
- Inhibitors of the Nonspecific Cation Channel: Natriuretic Peptides

PART II: WATER HOMEOSTASIS AND THE VASOPRESSIN SYSTEM
- Vasopressin Physiology
- Vasopressin Receptor Agonists
- Diseases Affecting the Vasopressin System
- Clinical Use of Vasopressin Agonists
- Clinical Use of Vasopressin Antagonists

The kidney filters the extracellular fluid volume across the renal glomeruli an average of 12 times a day, and the renal nephrons precisely regulate the fluid volume of the body and its electrolyte content via processes of secretion and reabsorption. Disease states such as hypertension, heart failure, renal failure, nephrotic syndrome, and cirrhosis may disrupt this balance. Diuretics increase the rate of urine flow and Na⁺ excretion and are used to adjust the volume or composition of body fluids in these disorders. Precise regulation of body fluid osmolality is essential. It is controlled by a finely tuned homeostatic mechanism that operates by adjusting both the rate of water intake and the rate of solute-free water excretion by the kidneys—that is, water balance. Abnormalities in this homeostatic system can result from genetic diseases, acquired diseases, or drugs and may cause serious and potentially life-threatening deviations in plasma osmolality.

Part I of this chapter first describes renal physiology, then introduces diuretics with regard to mechanism and site of action, effects on urinary composition, and effects on renal hemodynamics, and then integrates diuretic pharmacology with a discussion of mechanisms of edema formation and the role of diuretics in clinical medicine. Specific therapeutic applications of diuretics are presented in Chapters 28 (hypertension) and 29 (heart failure). Part II of this chapter describes the vasopressin system that regulates water homeostasis and plasma osmolality and factors that perturb those mechanisms and examines pharmacological approaches for treating disorders of water balance.

Glomerular Filtration
In the glomerular capillaries, a portion of plasma water is forced through a filter that has three basic components: the fenestrated capillary endothelial cells, a basement membrane lying just beneath the endothelial cells, and the filtration slits diaphragms formed by epithelial cells that cover the basement membrane on its urinary space side. Solutes of small size flow with filtered water (solvent drag) into Bowman's space, whereas formed elements and macromolecules are retained by the filtration barrier.

Overview of Nephron Function
The kidney filters large quantities of plasma, reabsorbs substances that the body must conserve, and leaves behind or secretes substances that must be eliminated. The changing architecture and cellular differentiation along the length of a nephron are crucial to these functions (see Figure 25–1). The two kidneys in humans together produce about 120 mL of ultrafiltrate/min, yet only 1 mL of urine/min of urine; more than 99% of the glomerular ultrafiltrate is reabsorbed at a staggering energy cost. The kidneys consume 7% of total-body O₂ intake despite comprising only 0.5% of body weight.

The proximal tubule is contiguous with Bowman's capsule and takes a tortuous path until finally forming a straight portion that dives into the renal medulla. Normally, about 65% of filtered Na⁺ is reabsorbed in the proximal tubule, and because this part of the tubule is highly permeable to water, reabsorption is essentially isotonic. Between the outer and inner strips of the outer medulla, the tubule abruptly changes morphology to become the DTL, which penetrates the inner medulla, makes a hairpin turn, and then forms the ATL. At the juncture between the inner and outer medulla, the tubule once again changes morphology and becomes the TAL. Together, the proximal straight tubule, DTL, ATL, and TAL segments are known as the loop of Henle.

The DTL is highly permeable to water, yet its permeabilities to NaCl and urea are low. In contrast, the ATL is permeable to NaCl and urea but is impermeable to water. The TAL actively reabsorbs NaCl but is impermeable to water and urea. Approximately 25% of filtered Na⁺ is reabsorbed in the loop of Henle, mostly in the TAL, which has a large reabsorptive capacity. The TAL passes between the afferent and efferent arterioles and makes contact with the afferent arteriole by means of a cluster of specialized columnar epithelial cells known as the macula densa. The macula densa is strategically located to sense concentrations of NaCl leaving the loop of Henle. If the concentration of NaCl is too
Abbreviations

AA: arachidonic acid
ACTH: corticotropin (previously adrenocorticotropic hormone)
ADH: antidiuretic hormone
AIP: aldosterone-induced protein
Aldo: aldosterone
Ang: angiotensin
ANP: atrial natriuretic peptide
ATL: ascending thin limb
AVP: arginine vasopressin
BL: basolateral membrane
BNP: brain natriuretic peptide
Ca: carbonic anhydrase
cGMP: cyclic guanosine monophosphate
CHF: congestive heart failure
CNCC: cyclic nucleotide-gated cation channel
CNP: C-type natriuretic peptide
CNT: connecting tubule
COX: cyclooxygenase
DAG: diacylglycerol
dCT: distal convoluted tubule
DDAVP: 1-deamino-8-D-avp (desmopressin)
Dl: diabetes insipidus
dTL: descending thin limb
eCFV: extracellular fluid volume
ENaC: epithelial Na+ channel
ENCC1 or TSC: the absorptive Na+-Cl− symporter
ENCC2, NKKC2, or BSC2: the absorptive Na+-K+-2Cl−
ENCC3, NKKC1, or BSC1: the secretory symporter
FDA: Food and Drug Administration
FF: filtration fraction
GFR: glomerular filtration rate
GPCR: G protein–coupled receptor
GTP: guanosine triphosphate
HCTZ: hydrochlorothiazide
HDL: high-density lipoprotein
HSD: 11-β-hydroxysteroid dehydrogenase
IMCD: inner medullary collecting duct
IP3: inositol triphosphate
LDL: low-density lipoprotein
LM: luminal membrane
LOX: lipoxygenase
LT: leukotriene
MR: mineralocorticoid receptor
MRA: mineralocorticoid receptor antagonist
mRNA: messenger RNA
Na: natriuretic peptide
NPA: asparagine-proline-alanine
NPR: natriuretic peptide receptor—an (e.g., NPRA, B, or C)
NSAID: nonsteroidal anti-inflammatory drug
OAT: organic anion transporter
PA: phosphatidic acid
PG: prostaglandin
PK: protein kinase—an (e.g., PKA, PKB, PKG)
PL: phospholipase—an (e.g., PLC, PLD)
PTH: parathyroid hormone
PVN: paraventricular nucleus
RAAS: renin-angiotensin-aldosterone system
RAS: renin-angiotensin system
RBF: renal blood flow
SGK-1: serum and glucocorticoid-stimulated kinase 1
SIADH: syndrome of inappropriate secretion of ADH

SNS: sympathetic nervous system
SON: supraoptic nucleus
TAL: thick ascending limb
TGF: tubuloglomerular feedback
TX: thromboxane
VP: vasopressin
VRUT: vasopressin-regulated urea transporter
vWD: von Willebrand disease
WCV: water channel-containing vesicle

high, the macula densa sends a chemical signal (perhaps adenosine or ATP) to the afferent arteriole of the same nephron, causing it to constrict, thereby reducing the GFR. This homeostatic mechanism, known as TGF, protects the organism from salt and volume wasting. The macula densa also regulates renin release from the adjacent juxtaglomerular cells in the wall of the afferent arteriole.

Approximately 0.2 mm past the macula densa, the tubule changes morphology once again to become the DCT. Like the TAL, the DCT actively transports NaCl and is impermeable to water. Because these characteristics impart the capacity to produce dilute urine, the TAL and the DCT are collectively called the diluting segment of the nephron, and the tubular fluid in the DCT is hypotonic regardless of hydration status. However, unlike the TAL, the DCT does not contribute to the countercurrent-induced hypertonicity of the medullary interstitium (described in material that follows).

The collecting duct system (segments 10–14 in Figure 25–1) is an area of fine control of ultrafiltrate composition and volume. It is here that final adjustments in electrolyte composition are made, a process modulated by the adrenal steroid aldosterone. Vasopressin (also called ADH) modulates water permeability of this part of the nephron as well. The more distal portions of the collecting duct pass through the renal medulla, where the interstitial fluid is markedly hypertonic. In the absence of ADH, the collecting duct system is impermeable to water, and dilute urine is excreted. In the presence of ADH, the collecting duct system is permeable to water, and water is reabsorbed. The movement of water out of the tubule is driven by the steep concentration gradient that exists between tubular fluid and medullary interstitium.

The hypertonicity of the medullary interstitium plays a vital role in the capacity of mammals and birds to concentrate urine, which is accomplished by a combination of the unique topography of the loop of Henle and the specialized permeabilities of the loop’s subsegments. The “passive countercurrent multiplier hypothesis” proposes that active transport in the TAL concentrates NaCl in the interstitium of the outer medulla. Because this segment of the nephron is impermeable to water, active transport in the ascending limb dilutes the tubular fluid. As the dilute fluid passes into the collecting duct system, water is extracted if, and only if, ADH is present. Because the cortical and outer medullary collecting ducts have low permeability to urea, urea is concentrated in the tubular fluid. The IMCD, however, is permeable to urea, so urea diffuses into the inner medulla, where it is trapped by countercurrent exchange in the vasa recta (medullary capillaries that run parallel to the loop of Henle). Because the DTL is impermeable to salt and urea, the high urea concentration in the inner medulla extracts water from the DTL and concentrates NaCl in the tubular fluid of the DTL. As the tubular fluid enters the ATL, NaCl diffuses out of the salt-permeable ATL, thus contributing to the hypertonicity of the medullary interstitium.

**General Mechanism of Renal Epithelial Transport**

There are multiple mechanisms by which solutes may cross cell membranes (see Figure 5–4). The kinds of transport achieved in a nephron segment depend mainly on which transporters are present and whether they are embedded in the luminal or basolateral membrane. Figure 25–2 presents a general model of renal tubular transport that be summarized as follows:

1. Na+, K+-ATPase (sodium pump) in the basolateral membrane transports Na+ into the intercellular and interstitial spaces and K+ into the cell,
establishing an electrochemical gradient for Na\(^+\) across the cell membrane directed inward.

2. Na\(^+\) can diffuse down this Na\(^+\) gradient across the luminal membrane via Na\(^+\) channels and via membrane symporters that use the energy stored in the Na\(^+\) gradient to transport solutes out of the tubular lumen and into the cell (e.g., Na\(^+\)-glucose, Na\(^+\)-H\(_2\)PO\(_4\)\(^-\), and Na\(^+\)-amino acid) and antiporters (e.g., Na\(^+\)-H\(^+\)) that move solutes into the lumen as Na\(^+\) moves down its gradient and into the cell.

3. Na\(^+\) exits the basolateral membrane into intercellular and interstitial spaces via the Na\(^+\) pump.

4. The action of Na\(^+\)-linked symporters in the luminal membrane causes the concentration of substrates for these symporters to rise in the epithelial cell. These substrate/solute gradients then permit simple diffusion or mediated transport (e.g., symporters, antiporters, uniporters, and channels) of solutes into the intercellular and interstitial spaces.

5. Accumulation of Na\(^+\) and other solutes in the intercellular space creates a small osmotic pressure differential across the epithelial cell. In water-permeable epithelium, water moves into the intercellular spaces driven by the osmotic pressure differential. Water moves through aqueous pores in both the luminal and the basolateral cell membranes,
as well as through tight junctions (paracellular pathway). Bulk water flow carries some solutes into the intercellular space by solvent drag.

6. Movement of water into the intercellular space concentrates other solutes in the tubular fluid, resulting in an electrochemical gradient for these substances across the epithelium. Membrane-permeable solutes then move down their electrochemical gradients into the intercellular space by both the transcellular (e.g., simple diffusion, symporters, antiporters, uniporters, and channels) and paracellular pathways. Membrane-impermeable solutes remain in the tubular lumen and are excreted in the urine with an obligatory amount of water.

7. As water and solutes accumulate in the intercellular space, hydrostatic pressure increases, thus providing a driving force for bulk water flow. Bulk water flow carries solute out of the intercellular space into the interstitial space and, finally, into the peritubular capillaries.

**Organic Acid and Organic Base Secretion**

The kidney is a major organ involved in the elimination of organic chemicals from the body. Organic molecules may enter the renal tubules by glomerular filtration or may be actively secreted directly into tubules. The proximal tubule has a highly efficient transport system for organic acids and an equally efficient but separate transport system for organic bases. Current models for these secretory systems are illustrated in Figure 25–3. Both systems are powered by the sodium pump in the basolateral membrane, involve secondary and tertiary active transport, and use a facilitated diffusion step. There are many organic acid and organic base transporters (see Chapter 5). A family of OATs links countertransport of organic anions with dicarboxylates (Figure 25–3A).

**Renal Handling of Specific Anions and Cations**

Reabsorption of Cl⁻ generally follows reabsorption of Na⁺. In segments of the tubule with low-resistance tight junctions (i.e., “leaky” epithelium), such as the proximal tubule and TAL, Cl⁻ movement can occur paracellularly. Cl⁻ crosses the luminal membrane by antiport with formate and oxalate (proximal tubule), symport with Na⁺/K⁺ (TAL), symport with Na⁺ (DCT), and antiport with HCO₃⁻ (collecting duct system). Cl⁻ crosses the basolateral membrane via symport with K⁺ (proximal tubule and TAL), antiport with Na⁺/HCO₃⁻ (proximal tubule), and Cl⁻ channels (TAL, DCT, collecting duct system).
Diuretics are drugs that increase the rate of urine flow; clinically useful diuretics also increase the rate of Na+ excretion (natriuresis) and of an accompanying anion, usually Cl−. Most clinical applications of diuretics are directed toward reducing extracellular fluid volume by decreasing total-body NaCl content.

Although continued diuretic administration causes a sustained net deficit in total-body Na+, the time course of natriuresis is finite because renal compensatory mechanisms bring Na+ excretion in line with Na+ intake, a phenomenon known as diuretic braking. These compensatory mechanisms include activation of the sympathetic nervous system, activation of the renin-angiotensin-aldosterone axis, decreased arterial blood pressure (which reduces pressure natriuresis), renal epithelial cell hypertrophy, increased renal epithelial transporter expression, and perhaps alterations in natriuretic hormones such as ANP. The net effects on extracellular volume and body weight are shown in Figure 25–4.

Diuretics may modify renal handling of other cations (e.g., K+, H+, Ca++, and Mg++) and anions (e.g., Cl−, HCO−3, and H2PO−4), and uric acid. In addition, diuretics may alter renal hemodynamics indirectly. Table 25–1 compares the general effects of the major diuretic classes.

Inhibitors of Carbonic Anhydrase
There are three orally administered carbonic anhydrase inhibitors—acetazolamide, dichlorphenamide, and methazolamide (Table 25–2).

Mechanism and Site of Action
Proximal tubular epithelial cells are richly endowed with the zinc metalloenzyme carbonic anhydrase, which is found in the luminal and basolateral membranes (type IV carbonic anhydrase), as well as in the cytoplasm (type II carbonic anhydrase) (Figure 25–5). Carbonic anhydrase plays a role in NaHCO3 reabsorption and acid secretion.

*Except for uric acid, changes are for acute effects of diuretics in the absence of significant volume depletion, which would trigger complex physiological adjustments.

*H includes titratable acid and NH₄⁺.

In general, these effects are restricted to those individual agents that inhibit carbonic anhydrase. However, there are notable exceptions in which symport inhibitors increase bicarbonate and phosphate (e.g., metolazone, bumetanide). ++, +, (+), −, NC, V (+), V(–) and I indicate marked increase, mild-to-moderate increase, slight increase, decrease, no change, variable effect, variable increase, variable decrease, and insufficient data, respectively. For cations and anions, the indicated effects refer to absolute changes in fractional excretion.

---

**Figure 25–5 Sites and mechanisms of action of diuretics.** Three important features are noteworthy: 1. Transport of solute across epithelial cells in all nephron segments involves highly specialized proteins, which for the most part are apical and basolateral membrane integral proteins. 2. Diuretics target and block the action of epithelial proteins involved in solute transport. 3. The site and mechanism of action of a given class of diuretics are determined by the specific protein inhibited by the diuretic.
In the proximal tubule, the free energy in the Na⁺ gradient established by the basolateral Na⁺ pump is used by a Na⁺-H⁺ antiporter (Na⁺-H⁺ exchanger type 3) in the luminal membrane to transport H⁺ into the tubular lumen in exchange for Na⁺. In the lumen, H⁺ reacts with filtered HCO₃⁻ to form H₂CO₃, which decomposes rapidly to CO₂ and water in the presence of carbonic anhydrase in the brush border. Carbonic anhydrase reversibly accelerates this reaction several thousand fold. CO₂ is lipophilic and rapidly diffuses across the luminal membrane into the epithelial cell, where it reacts with water to form H₂CO₃, a reaction catalyzed by cytoplasmic carbonic anhydrase. Continued operation of the Na⁺-H⁺ antiporter maintains a low proton concentration in the cell, so H₂CO₃ ionizes spontaneously to form H⁺ and HCO₃⁻, creating an electrochemical gradient for HCO₃⁻ across the basolateral membrane. The electrochemical gradient for HCO₃⁻ is used by a Na⁺-HCO₃⁻ symporter (also known as the Na⁺-HCO₃⁻ cotransporter) in the basolateral membrane to transport NaHCO₃ into the interstitial space. The net effect of this process is transport of NaHCO₃ from the tubular lumen to the interstitial space, followed by movement of water (isotonic reabsorption). Removal of water concentrates Cl⁻ in the tubular lumen, and consequently, Cl⁻ diffuses down its concentration gradient into the interstitium by the paracellular pathway.

Carbonic anhydrase inhibitors potently inhibit both the membrane-bound and cytoplasmic forms of carbonic anhydrase, and can cause nearly complete abolition of NaHCO₃ reabsorption in the proximal tubule. However, due to the large excess of carbonic anhydrase activity in proximal tubules, a large fraction of the enzyme activity must be inhibited before an effect on electrolyte excretion is observed. Although the proximal tubule is the major site of action of carbonic anhydrase inhibitors, carbonic anhydrase also is involved in secretion of titratable acid in the collecting duct system, which is a secondary site of action for this class of drugs.

### Effects on Urinary Excretion
Inhibition of carbonic anhydrase is associated with a rapid rise in urinary HCO₃⁻ excretion to about 35% of filtered load. This, along with inhibition of titratable acid and NH₄⁺ secretion in the collecting duct system, results in an increase in urinary pH to about 8 and development of metabolic acidosis. However, even with a high degree of inhibition of carbonic anhydrase, 65% of HCO₃⁻ is rescued from excretion. The loop of Henle has large reabsorptive capacity and captures most of the Cl⁻ and a portion of the Na⁺. Thus, only a small increase in Cl⁻ excretion occurs. HCO₃⁻ being the major anion excreted along with the cations Na⁺ and K⁺. The fractional excretion of Na⁺ may be as much as 5%, and the fractional excretion of K⁺ can be as much as 70%. The increased excretion of K⁺ is in part secondary to increased delivery of Na⁺ to the distal nephron, as described in the section on inhibitors of Na⁺ channels. The effects of carbonic anhydrase inhibitors on renal excretion are self-limiting, probably because the resulting metabolic acidosis decreases the filtered load of HCO₃⁻; to the point that the uncatalyzed reaction between CO₂ and water is sufficient to achieve HCO₃⁻ reabsorption.

### Effects on Renal Hemodynamics
By inhibiting proximal reabsorption, carbonic anhydrase inhibitors increase delivery of solutes to the macula densa. This triggers TGF, which increases afferent arteriolar resistance and reduces RBF and GFR.

### Other Actions
These agents have extrarenal sites of action. Carbonic anhydrase in the ciliary processes of the eye mediates formation of HCO₃⁻ in aqueous humor. Inhibition of carbonic anhydrase decreases the rate of formation of aqueous humor and consequently reduces intraocular pressure. Acetazolamide frequently causes paresthesias and somnolence, suggesting an action of carbonic anhydrase inhibitors in the CNS. The efficacy of acetazolamide in epilepsy is due in part to the production of metabolic acidosis; however, direct actions of acetazolamide in the CNS also contribute to its anticonvulsant action. Owing to interference with carbonic anhydrase activity in erythrocytes, carbonic anhydrase inhibitors increase CO₂ levels in peripheral tissues and decrease CO₂ levels in expired gas. Acetazolamide causes vasodilation by opening vascular Ca²⁺-activated K⁺ channels; however, the clinical significance of this effect is unclear.

### Toxicity, Adverse Effects, Contraindications, Drug Interactions
Serious toxic reactions to carbonic anhydrase inhibitors are infrequent; however, these drugs are sulfonamide derivatives and, like other sulfonamides, may cause bone marrow depression, skin toxicity, sulfonamide-like renal lesions, and allergic reactions. With large doses, many patients exhibit drowsiness and paresthesias. Most adverse effects, contraindications, and drug interactions are secondary to urinary alkalization or metabolic acidosis, including (1) diversion of ammonia of renal origin from urine into the systemic circulation, a process that may induce or worsen hepatic encephalopathy (the drugs are contraindicated in patients with hepatic cirrhosis); (2) calculus formation and ureteral colic owing to precipitation of calcium phosphate salts in alkaline urine; (3) worsening of metabolic or respiratory acidosis (the drugs are contraindicated in patients with hyperchloremic acidosis or severe chronic obstructive pulmonary disease); and (4) reduction of the urinary excretion rate of weak organic bases.

### Osmotic Diuretics
Osmotic diuretics (Table 25–3) are freely filtered at the glomerulus, undergo limited reabsorption by the renal tubule, and are relatively inert pharmacologically. Osmotic diuretics are administered in doses large enough to increase significantly the osmolarity of plasma and tubular fluid. Of the osmotic diuretics listed, only glycerin and mannitol are currently available in the U.S.

### Therapeutic Uses
The efficacy of carbonic anhydrase inhibitors as single agents is low. The combination of acetazolamide with diuretics that block Na⁺ reabsorption at more distal sites in the nephron causes a marked natriuretic response in patients with low basal fractional excretion of Na⁺ (<0.2%) who are resistant to diuretic monotherapy. Even so, the long-term usefulness of carbonic anhydrase inhibitors often is compromised by the development of metabolic acidosis. The major indication for carbonic anhydrase inhibitors is open-angle glaucoma (Scozzafava and Supuran, 2014). Two products developed specifically for this use are dorzolamide and brinzolamide, which are available only as ophthalmic drops. Carbonic anhydrase inhibitors also may be employed for secondary glaucoma and preoperatively in acute-angle closure glaucoma to lower intraocular pressure before surgery (see Chapter 69). Orally administered acetazolamide also is used for the treatment of glaucoma (see Chapter 69) and absence seizures (see Chapter 21). Acetazolamide can provide symptomatic relief in patients with high-altitude illness or mountain sickness (Ritchie et al., 2012). Carbonic anhydrase inhibitors are also useful in patients with familial periodic paralysis. Dichlorphenamide is now approved for treating this syndrome. The mechanism for the beneficial effects of carbonic anhydrase inhibitors in altitude sickness and familial periodic paralysis may relate to the induction of a metabolic acidosis. Finally, carbonic anhydrase inhibitors can be useful for correcting metabolic alkalosis, especially one caused by diuretic-induced increases in H⁺ excretion.
**Mechanism and Site of Action**

Osmotic diuretics act in both the proximal tubule and the loop of Henle, with the latter the primary site of action. In the proximal tubule, osmotic diuretics act as nonreabsorbable solutes that limit the osmosis of water into the interstitial space and thereby reduce the luminal Na+ concentration to the point that net Na+ reabsorption ceases. By extracting water from intracellular compartments, osmotic diuretics expand extracellular fluid volume, decrease blood viscosity, and inhibit renin release. These effects increase RBF, and the increase in renal medullary blood flow removes NaCl and urea from the renal medulla, thus reducing medullary toxicity. A reduction in medullary toxicity causes a decrease in the extraction of water from the DTL, which in turn limits the concentration of NaCl in the tubular fluid entering the ATL. This latter effect diminishes the passive reabsorption of NaCl in the ATL. In addition, osmotic diuretics inhibit Mg2+ reabsorption in the TAL.

**Effects on Urinary Excretion**

Osmotic diuretics increase urinary excretion of nearly all electrolytes, including Na+, K+, Ca2+, Mg2+, Cl−, HCO3−, and phosphate.

**Effects on Renal Hemodynamics**

Osmotic diuretics increase RBF by a variety of mechanisms, but total GFR is little changed.

**ADME**

Pharmacokinetic data on the osmotic diuretics are gathered in Table 25–3. Where available, glycerin and isosorbide can be given orally, whereas mannitol and urea must be administered intravenously (with the exception that mannitol powder is used by inhalation for diagnosis of bronchial hyperreactivity).

**Therapeutic Uses**

One use for mannitol is in the treatment of dialysis disequilibrium syndrome. Overly removing solutes from the extracellular fluid by hemodialysis results in a reduction in the osmolality of extracellular fluid. Consequently, water moves from the extracellular compartment into the intracellular compartment, causing hypotension and CNS symptoms (headache, nausea, muscle cramps, restlessness, CNS depression, and convulsions). Osmotic diuretics increase the osmolality of the extracellular fluid compartment and thereby shift water back into the extracellular compartment. By increasing the osmotic pressure of plasma, osmotic diuretics extract water from the eye and brain. Osmotic diuretics are used to control intraocular pressure during acute attacks of glaucoma and for short-term reductions in intraocular pressure both preoperatively and postoperatively in patients who require ocular surgery. Also, mannitol is used to reduce cerebral edema and brain mass before and after neurosurgery and to control intracranial pressure in patients with traumatic brain injury (Wakai et al., 2013). Mannitol is often used to treat or prevent acute kidney injury; however, it is questionable regarding whether mannitol improves renal outcomes (Nigwekar and Waikar, 2011). Other FDA-approved uses of mannitol include enhancement of urinary excretion of salicylates, barbiturates, bromides, and lithium following overdose; for the diagnosis of bronchial hyperreactivity (by oral inhalation); and for antimicrobial urologic irrigation during transurethral procedures.

**Toxicity, Adverse Effects, Contraindications, and Drug Interactions**

Osmotic diuretics are distributed in the extracellular fluid and contribute to the extracellular osmolality. Thus, water is extracted from intracellular compartments, and the extracellular fluid volume becomes expanded. In patients with heart failure or pulmonary congestion, this may cause frank pulmonary edema. Extraction of water also causes hypotension, which may explain the common adverse effects, including headache, nausea, and vomiting. Conversely, loss of water in excess of electrolytes can cause hypernatremia and dehydration. Osmotic diuretics are contraindicated in patients who are anuric owing to severe renal disease. Urea may cause thrombosis or pain if extravasation occurs, and it should not be administered to patients with impaired liver function because of the risk of elevation of blood ammonia levels. Both mannitol and urea are contraindicated in patients with active cranial bleeding. Glycerin is metabolized and can cause hyperglycemia.

**Inhibitors of Na+-K+-2Cl− Symport: Loop Diuretics, High-Ceiling Diuretics**

The loop and high-ceiling diuretics inhibit activity of the Na+-K+-2Cl− symporter in the TAL of the loop of Henle, hence the moniker loop diuretics. Although the proximal tubule reabsorbs about 65% of filtered Na+, diuretics acting only in the proximal tubule have limited efficacy because the TAL has the capacity to reabsorb most of the rejectate from the proximal tubule. In contrast, inhibitors of Na+-K+-2Cl− symport in the TAL, sometimes called high-ceiling diuretics, are highly efficacious because (1) about 25% of the filtered Na+ load normally is reabsorbed by the TAL, and (2) nephron segments past the TAL do not possess the resorptive capacity to rescue the flood of rejectate exiting the TAL.

Of the inhibitors of Na+-K+-2Cl− symport (Table 25–4), only furosemide, bumetanide, ethacrynic acid, and torsemide are available in the U.S. Furosemide and bumetanide contain a sulfonamide moiety. Ethacrynic acid is a phenoxyacetic acid derivative; torsemide is a sulfonamide. Furosemide and bumetanide are available as oral and injectable formulations. Torsemide is available as an oral formulation; ethacrynate sodium is available as an injectable solution and ethacrynic acid as an oral tablet.

**Mechanism and Site of Action**

These agents act primarily in the TAL, where the flux of Na+, K+, and Cl− from the lumen into epithelial cells is mediated by a Na+-K+-2Cl− symporter (Figure 25–5). Inhibitors of this symporter block its function (Bernstein and Ellison, 2011; Wile, 2012), bringing salt transport in this segment of the nephron to a virtual standstill. There is evidence that these

†Metabolism of furosemide occurs predominantly in the kidney.
‡Not available in the U.S.
drugs attach to the Cl− binding site located in the symporter’s transmembrane domain; however, more recent studies challenge this view. Inhibitors of Na+-K+-2Cl− symport also inhibit Ca2+ and Mg2+ reabsorption in the TAL by abolishing the transepithelial potential difference that is the dominant driving force for reabsorption of these cations.

Na+-K+-2Cl− symporters are found in many secretory and absorbing epithelia. There are two varieties of Na+-K+-2Cl− symporters. The “absorptive” symporter (called ENCC2, NKCC2, or BSC2) is expressed only in the kidney, is localized to the apical membrane and subapical intracellular vesicles of the TAL, and is regulated by the cyclic AMP/PKA pathway. The “secretory” symporter (called ENCC1, NKCC1, or BSC1) is a “housekeeping” protein that is expressed widely and, in epithelial cells, is localized to the basolateral membrane. The affinity of loop diuretics for the secretory symporter is somewhat less than for the absorptive symporter (e.g., 4-fold difference for bumetanide). Mutations in the Na+-K+-2Cl− symporter cause a form of inherited hypokalemic alkalosis called Bartter syndrome.

**Effects on Urinary Excretion**

Loop diuretics increase urinary Na+ and Cl− excretion profoundly (i.e., up to 25% of the filtered Na+ load) and markedly increase Ca2+ and Mg2+ excretion. Furosemide has weak carbonic anhydrase–inhibiting activity and thus increases urinary excretion of HCO3− and phosphate. All inhibitors of Na+-K+-2Cl− symport increase urinary K+ and titratable acid excretion. This effect is due in part to increased Na+ delivery to the distal tubule (the mechanism by which increased distal Na+ delivery enhances K+ and H+ excretion is discussed in the section on Na+ channel inhibitors). Other mechanisms contributing to enhanced K+ and H+ excretion include flow-dependent enhancement of ion secretion by the collecting duct, nonosmotic vasopressin release, and activation of the RAS axis.

Acutely, loop diuretics increase uric acid excretion; their chronic administration results in reduced uric acid excretion. Chronic effects of loop diuretics on uric acid excretion may be due to enhanced proximal tubule transport or secondary to volume depletion or to competition between diuretic and uric acid for the organic acid secretory mechanism in the proximal tubule. Asymptomatic hyperuricemia is a common consequence of loop diuretics, but painful episodes of gout are rarely reported. By blocking active NaCl reabsorption in the TAL, inhibitors of Na+-K+-2Cl− symport interfere with a critical step in the mechanism that produces a hypertonic medullary interstitium. Therefore, loop diuretics block the kidney’s ability to concentrate urine. Also, because the TAL is part of the diluting segment, inhibitors of Na+-K+-2Cl− symport markedly impair the kidney’s ability to excrete a dilute urine during water diuresis.

**Effects on Renal Hemodynamics**

If volume depletion is prevented by replacing fluid losses, inhibitors of Na+-K+-2Cl− symport generally increase total RBF and redistribute RBF to the midcortex. The mechanism of the increase in RBF is not known but may involve PGs. NSAIDs attenuate the diuretic response to loop diuretics in part by preventing PG-mediated increases in RBF. Loop diuretics block TGF by inhibiting salt transport into the macula densa so that the macula densa no longer detects NaCl concentrations in the tubular fluid. Therefore, unlike carbonic anhydrase inhibitors, loop diuretics do not decrease the GFR by activating TGF. Loop diuretics are powerful stimulators of renin release. This effect is due to interference with NaCl transport by the macula densa and, if volume depletion occurs, to reflex activation of the sympathetic nervous system and stimulation of the intrarenal baroreceptor mechanism.

**Other Actions**

Loop diuretics, particularly furosemide, acutely increase systemic venous capacitance and thereby decrease left ventricular filling pressure. This effect, which may be mediated by PGs and requires intact kidneys, benefits patients with pulmonary edema even before diuresis ensues. High doses of inhibitors of Na+-K+-2Cl− symport can inhibit electrolyte transport in many tissues. This effect is clinically important in the inner ear and can result in ototoxicity, particularly in patients with preexisting hearing impairment.

**ADME**

Table 25–4 presents some pharmacokinetic properties of the agents. Because these drugs are bound extensively to plasma proteins, delivery of these drugs to tubules by filtration is limited. However, they are secreted efficiently by the organic acid transport system in the proximal tubule and thereby gain access to the Na+-K+-2Cl− symporter in the luminal membrane of the TAL. Approximately 65% of furosemide is excreted unchanged in urine, and the remainder is conjugated to glucuronic acid in the kidney. Thus, in patients with renal disease, the elimination t1/2 of furosemide is prolonged. Bumetanide and torsemide have significant hepatic metabolism, so liver disease can prolong the elimination t1/2 of these loop diuretics. Oral bioavailability of furosemide varies (10%–100%). In contrast, oral availabilities of bumetanide and torsemide are reliably high. As a class, loop diuretics have short elimination half-lives; prolonged-release preparations are not available. Consequently, often the dosing interval is too short to maintain adequate levels of loop diuretics in the tubular lumen. Note that torsemide has a longer t1/2 than other agents available in the U.S. As the concentration of loop diuretic in the tubular lumen declines, nephrons begin to avidly reabsorb Na+, which often nullifies the overall effect of the loop diuretic on total-body Na+. This phenomenon of “postdiuretic Na+ retention” can be overcome by restricting dietary Na+ intake or by more frequent administration of the loop diuretic.

**Therapeutic Uses**

A major use of loop diuretics is in the treatment of acute pulmonary edema. A rapid increase in venous capacitance in conjunction with brisk natriuresis reduces left ventricular filling pressures and thereby rapidly relieves pulmonary edema. Loop diuretics also are used widely for treatment of chronic CHF when diminution of extracellular fluid volume is desirable to minimize venous and pulmonary congestion (see Chapter 29). Diuretics cause a significant reduction in mortality and the risk of worsening heart failure, as well as an improvement in exercise capacity. Although furosemide is the most commonly used loop diuretic for the treatment of heart failure, patients with heart failure have fewer hospitalizations and better quality of life with torsemide than with furosemide, perhaps because of its more reliable absorption and due to other ancillary pharmacological effects (Buggey et al., 2015).

Although diuretics are used widely for treatment of hypertension (see Chapter 28), in patients with normal renal function, Na+-K+-2Cl− symport inhibitors are not considered first-line diuretics for the treatment of hypertension. This is due to the lower antihypertensive efficacy of loop diuretics in such patients and the lack of data demonstrating a reduction in cardiovascular events. However, in patients with a low GFR (<30 mL/min) or with resistant hypertension, loop diuretics are the diuretics of choice.

The edema of nephrotic syndrome often is refractory to less potent diuretics, and loop diuretics often are the only drugs capable of reducing the massive edema associated with this renal disease. Loop diuretics also are employed in the treatment of edema and ascites of liver cirrhosis; however, care must be taken not to induce volume contraction. In patients with a drug overdose, loop diuretics can be used to induce forced diuresis to facilitate more rapid renal elimination of the offending drug. Loop diuretics, combined with isotonic saline administration to prevent volume depletion, are used to treat hypercalcemia. Loop diuretics interfere with the kidney’s capacity to produce concentrated urine. Consequently, loop diuretics combined with hypertonic saline are useful for the treatment of life-threatening hyponatremia. Loop diuretics also are used to treat edema associated with chronic kidney disease, in which the dose-response curve may be right shifted, requiring higher doses of the loop diuretic.

**Toxicity, Adverse Effects, Contraindications, Drug Interactions**

Most adverse effects are due to abnormalities of fluid and electrolyte balance. Overzealous use of loop diuretics can cause serious depletion of total-body Na+. This may manifest as hyponatremia or extracellular fluid volume depletion associated with hypotension, reduced GFR, circulatory collapse, thromboembolic episodes, and, in patients with liver disease, hepatic encephalopathy. Increased Na+ delivery to the
distal tubule, particularly when combined with activation of the renin-angiotensin system, leads to increased urinary K⁺ and H⁺ excretion, causing a hypochloremic alkalosis. If dietary K⁺ intake is not sufficient, hypokalemia may develop, and this may induce cardiac arrhythmias, particularly in patients taking cardiac glycosides. Increased Mg²⁺ and Ca²⁺ excretion may result in hypomagnesemia (a risk factor for cardiac arrhythmias) and hypocalcemia (rarely leading to tetany). Loop diuretics should be avoided in postmenopausal osteopenic women, in whom increased Ca²⁺ excretion may have deleterious effects on bone metabolism.

Loop diuretics can cause ototoxicity that manifests as tinnitus, hearing impairment, deafness, vertigo, and a sense of fullness in the ears. Hearing impairment and deafness are usually, but not always, reversible. Ototoxicity occurs most frequently with rapid intravenous administration and least frequently with oral administration. To avoid ototoxicity, the rate of furosemide infusions should not exceed 4 mg/min. Ethacrynic acid appears to induce ototoxicity more often than do other loop diuretics and should be reserved for use only in patients who cannot tolerate other loop diuretics. Loop diuretics also can cause hyperuricemia (influencing the risk of precipitation of diabetes mellitus) and can increase plasma levels of LDL cholesterol and triglycerides while decreasing plasma levels of HDL cholesterol. Other adverse effects include skin rashes, photosensitivity, paresthesias, bone marrow depression, and GI disturbances. Contraindications to the use of loop diuretics include severe Na⁺ and volume depletion, hypersensitivity to sulfonamides (for sulfonamide-based loop diuretics), and anuria unresponsive to a trial dose of loop diuretic.

Drug interactions may occur when loop diuretics are coadministered with the following:
- Aminoglycosides, carboplatin, paclitaxel, and others (synergism of ototoxicity)
- Anticoagulants (increased anticoagulant activity)
- Digitalis glycosides (increased digitalis-induced arrhythmias)
- Lithium (increased plasma levels of Li⁺)
- Propranolol (increased plasma levels of propranolol)
- Sulfonylureas (hyperglycemia)
- Cisplatin (increased risk of diuretic-induced ototoxicity)
- NSAIDs (blunted diuretic response and salicylate toxicity with high doses of salicylates)
- Probenecid (blunted diuretic response)
- Thiazide diuretics (synergism of diuretic activity of both drugs, leading to profound diuresis)
- Amphotericin B (increased potential for nephrotoxicity and intensification of electrolyte imbalance)

**Inhibitors of Na⁺-Cl⁻ Symport: Thiazide-Type and Thiazide-Like Diuretics**

The term thiazide diuretics generally refers to all inhibitors of Na⁺-Cl⁻ symport, so named because the original inhibitors of Na⁺-Cl⁻ symport were benzothiadiazine derivatives. The class now includes diuretics that are benzothiadiazine derivatives (thiazide or thiazide-type diuretics) and drugs that are pharmacologically similar to thiazide diuretics but differ structurally (thiazide-like diuretics). Table 25-5 lists diuretics in this drug class that are currently available in the United States.

**Mechanism and Site of Action**

Thiazide diuretics inhibit NaCl transport in the DCT; the proximal tubule may represent a secondary site of action. Figure 25-5 illustrates the current model of electrolyte transport in the DCT. Transport is powered by a Na⁺ pump in the basolateral membrane. Free energy in the electrochemical gradient for Na⁺ is harnessed by a Na⁺-Cl⁻ symporter in the luminal membrane that moves Cl⁻ into the epithelial cell against its electrochemical gradient. Cl⁻ then exits the basolateral membrane passively by a Cl⁻ channel. Thiazide diuretics inhibit the Na⁺-Cl⁻ symporter (called ENCC1 or TSC) that is expressed predominantly in kidney and localized to the apical membrane of DCT epithelial cells. Expression of the symporter is regulated by aldosterone. Mutations in the Na⁺-Cl⁻ symporter cause a form of inherited hypokalemic alkalosis called Gitelman syndrome.

**Effects on Urinary Excretion**

Inhibitors of Na⁺-Cl⁻ symport increase Na⁺ and Cl⁻ excretion. However, thiazides are only moderately efficacious (i.e., maximum excretion of filtered Na⁺ load is only 5%) because about 90% of the filtered Na⁺ load is reabsorbed before reaching the DCT. Some thiazide diuretics also are weak inhibitors of carbonic anhydrase, an effect that increases HCO₃⁻ and phosphate excretion and probably accounts for their weak proximal tubular effects. Inhibitors of Na⁺-Cl⁻ symport increase K⁺ and titratable acid excretion by the same mechanisms discussed for loop diuresis. Acute thiazide administration increases uric acid excretion. However, uric acid excretion is reduced following chronic administration by similar mechanisms discussed for loop diuretics. In addition, thiazides may be transported from the basolateral compartment to the luminal compartment via the OAT4 antiporter in the apical membrane (Palmer, 2011; see Chapter 5). Acute effects of inhibitors of Na⁺-Cl⁻ symport on Ca²⁺ excretion are variable; when administered chronically, thiazide diuretics decrease Ca²⁺ excretion. The mechanism involves increased proximal reabsorption owing to volume depletion, as well as direct effects of thiazides to increase Ca²⁺ reabsorption in the DCT. Thiazide diuretics may

cause mild magnesuria; long-term use of thiazide diuretics may cause magnesium deficiency, particularly in the elderly. Because inhibitors of Na⁺-Cl⁻ symport inhibit transport in the cortical diluting segment, thiazide diuretics attenuate the kidney's ability to excrete dilute urine during water diuresis. However, because the DCT is not involved in the mechanism that generates a hypertonic medullary interstitium, thiazide diuretics do not alter the kidney's ability to concentrate urine during diuresis. In general, inhibitors of Na⁺-Cl⁻ symport do not affect RBF and only variably reduce GFR owing to increases in intratubular pressure. Thiazides have little or no influence on TGF.

**ADME**

Table 25–5 lists pharmacokinetic parameters of Na⁺-Cl⁻ symport inhibitors. Note the wide range of half-lives for these drugs. Sulfonamides, as organic acids, are secreted into the proximal tubule by the organic acid secretory pathway. Because thiazides must gain access to the tubular lumen to inhibit the Na⁺-Cl⁻ symporter, drugs such as probenecid can attenuate the diuretic response to thiazides by competing for transport into the proximal tubule. However, plasma protein binding varies considerably among thiazide diuretics, and this parameter determines the contribution that filtration makes to tubular delivery of a specific thiazide.

**Therapeutic Uses**

Thiazide diuretics are used for the treatment of edema associated with diseases of the heart (CHF), liver (hepatic cirrhosis), and kidney (nephrotic syndrome, chronic renal failure, and acute glomerulonephritis). With the possible exceptions of metolazone and indapamide, most thiazide diuretics are ineffective when the GFR is less than 30–40 mL/min. Thiazide diuretics decrease blood pressure in hypertensive patients and are used widely for the treatment of hypertension in combination with other antihypertensive drugs (Tamargo et al., 2014) (see Chapter 28). Thiazide diuretics are inexpensive, as efficacious as other classes of antihypertensive agents, and well tolerated. Thiazides can be administered once daily, do not require dose titration, and have few contraindications. Moreover, thiazides have additive or synergistic effects when combined with other classes of antihypertensive agents. Although hydrochlorothiazide is the 10th most prescribed drug in the United States and is prescribed 20 times more often than chlorothalidone (Roush et al., 2014), there is strong evidence that chlorothalidone and other thiazide-like diuretics, such as indapamide, reduce blood pressure and cardiovascular events in hypertensive patients more so than does hydrochlorothiazide (Olde Engberink et al., 2015; Roush et al., 2014, 2015). This is likely due to the longer half-life of thiazide-like diuretics compared to hydrochlorothiazide, resulting in better 24-h control of arterial blood pressure by chlorothalidone.

Thiazide diuretics, which reduce urinary Ca²⁺ excretion, sometimes are employed to treat Ca²⁺ nephrolithiasis and may be useful for treatment of osteoporosis (see Chapter 44). Thiazide diuretics also are the mainstay for treatment of nesphogenic DI, reducing urinary volume by up to 50%. Although it may seem counterintuitive to treat a disorder of increased urine volume with a diuretic, thiazides reduce the kidney’s ability to excrete free water: They increase proximal tubular water reabsorption (secondary to volume contraction) and block the ability of the DCT to form dilute urine. This last effect results in an increase in urine osmolality. Because other haldes are excreted by renal processes similar to those for Cl⁻, thiazide diuretics may be useful for the management of Br⁻ intoxication.

**Toxicity, Adverse Effects, Contraindications, Drug Interactions**

Thiazide diuretics rarely cause CNS (e.g., vertigo, headache), GI, hematological, and dermatological (e.g., photosensitivity and skin rashes) disorders. The incidence of erectile dysfunction is greater with Na⁺-Cl⁻ symport inhibitors than with several other antihypertensive agents (Grimm et al., 1997), but usually is tolerable. As with loop diuretics, most serious adverse effects of thiazides are related to abnormalities of fluid and electrolyte balance. These adverse effects include extracellular volume depletion, hypotension, hypokalemia, hypotension, metabolic alkalosis, hypomagnesemia, hypercalcemia, and hyperuricemia (Palmer, 2011). Thiazide diuretics have caused fatal or near-fatal hyponatremia (Rodenburg et al., 2013), and some patients are at recurrent risk of hyponatremia when rechallenged with thiazides.

Thiazide diuretics also decrease glucose tolerance and unmask latent diabetes mellitus (Palmer, 2011). The mechanism of impaired glucose tolerance appears to involve reduced insulin secretion and alterations in glucose metabolism. Hyperglycemia is reduced when K⁺ is given along with the diuretic. Importantly, thiazide-induced diabetes mellitus is not associated with the same cardiovascular disease risk as incident diabetes (Barzilai et al., 2012). Thiazide-induced hypokalemia also impairs the antihypertensive effect and cardiovascular protection afforded by thiazides in patients with hypertension. Thiazide diuretics also may increase plasma levels of LDL cholesterol, total cholesterol, and total triglycerides. Thiazide diuretics are contraindicated in individuals who are hypersensitive to sulfonylamides. Thiazide diuretics may diminish the effects of anticoagulants, uricosuric agents used to treat gout, sulfonyleucares, and insulin and may increase the effects of anesthetics, diazoxide, digitalis glycosides, lithium, loop diuretics, and vitamin D. The effectiveness of thiazide diuretics may be reduced by NSAIDs, nonselective or selective COX-2 inhibitors, and bile acid sequestrants (reduced absorption of thiazides). Aminophylline B and corticosteroids increase the risk of hypokalemia induced by thiazide diuretics.

In a potentially lethal interaction, thiazide diuretic–induced K⁺ depletion may contribute to fatal ventricular arrhythmias associated with drugs that prolong the QT interval (i.e., quinidine, dofetilide, arsenic trioxide, see also Chapter 30).

**Inhibitors of Renal Epithelial Na⁺ Channels: K⁺-Sparing Diuretics**

Triamterene and amiloride are the only two drugs of this class in clinical use. Both drugs cause small increases in NaCl excretion and usually are employed for their antikaliuretic actions to offset the effects of other diuretics that increase K⁺ excretion. Consequently, triamterene and amiloride, along with spirronolactone and eplerenone (described in the next section), often are classified as potassium (K⁺)-sparing diuretics.

Both drugs are organic bases, are transported by the organic base secretory mechanism in the proximal tubule, and have similar mechanisms of action (Figure 25–5). Principal cells in the late distal tubules and collecting ducts (particularly cortical collecting tubules) have, in their luminal membranes, ENaCs that provide a conductive pathway for Na⁺ entry into the cell down the electrochemical gradient created by the basolateral Na⁺ pump. The higher permeability of the luminal membrane for Na⁺ depolarizes the luminal membrane but not the basolateral membrane, creating a lumen-negative transepithelial potential difference. This transepithelial voltage provides an important driving force for the secretion of K⁺ into the lumen via K⁺ channels (ROMK [Kirtl-1] and BK channels) (Garcia and Kaczorowski, 2014) in the luminal membrane; however, the overall regulation of K⁺ secretion in the late distal tubule and collecting duct involves multiple signaling mechanisms (Welling, 2013). Carbonic anhydrase inhibitors, loop diuretics, and thiazide diuretics increase Na⁺ delivery to the late distal tubule and collecting duct, a situation that often is associated with increased K⁺ and H⁺ excretion.

Amiloride and triamterene block ENaCs in the luminal membrane of principal cells in late distal tubules and collecting ducts by binding to a site in the channel pore. ENaCs consist of three subunits (α, β, and γ) (Kellenberger and Schild, 2015). Although the α subunit is sufficient for channel activity, maximal Na⁺ permeability is induced when all three subunits are coexpressed in the same cell, probably forming a tetrmeric structure consisting of two α subunits, one β subunit, and one γ subunit. Incompletely understood, complex mechanisms, including proteolytic cleavage, regulate ENaC activation (Kellenberger and Schild, 2015).

**Effects on Urinary Excretion**

The late distal tubule and collecting duct have a limited capacity to reabsorb solutes; thus, Na⁺ channel blockade in this part of the nephron increases Na⁺ and Cl⁻ excretion rates only mildly (~2% of filtered load).
Blockade of Na⁺ channels hyperpolarizes the luminal membrane, reducing the lumen-negative transepithelial voltage. Because the lumen-negative potential difference normally opposes cation reabsorption and facilitates cation secretion, attenuation of the lumen-negative voltage decreases K⁺, H⁺, Ca²⁺, and Mg²⁺ excretion rates. Volume contraction may increase reabsorption of uric acid in the proximal tubule; hence, chronic administration of amiloride and triamterene may decrease uric acid excretion. Amiloride and triamterene have little or no effect on renal hemodynamics and do not alter TGF.

**ADME**

Table 25–6 lists pharmacokinetic data for amiloride and triamterene. Amiloride is eliminated predominantly by urinary excretion of intact drug. Triamterene is metabolized in the liver to an active metabolite, 4-hydroxytriamterene sulfate, and this metabolite is excreted in urine. Therefore, triamterene toxicity may be enhanced in both hepatic disease and renal failure.

**Therapeutic Uses**

Because of the mild natriuresis induced by Na⁺ channel inhibitors, these drugs seldom are used as sole agents in treatment of edema or hypertension; their major utility is in combination with other diuretics. Coadministration of a Na⁺ channel inhibitor augments the diuretic and antihypertensive response to thiazide and loop diuretics. More important, the ability of Na⁺ channel inhibitors to reduce K⁺ excretion tends to offset the kaliuretic effects of thiazide and loop diuretics and to result in normal plasma K⁺ values.

Liddle syndrome (described later in this chapter) can be treated effectively with Na⁺ channel inhibitors. Aerosolized amiloride has been shown to improve mucociliary clearance in patients with cystic fibrosis. By inhibiting Na⁺ absorption from the surfaces of airway epithelial cells, amiloride augments hydration of respiratory secretions and thereby improves mucociliary clearance. Amiloride also is useful for lithium-induced nephrogenic DI because it blocks Li⁺ transport into collecting tubule cells (Kortenoeven et al., 2009).

**Toxicity, Adverse Effects, Contraindications, Drug Interactions**

The most dangerous adverse effect of renal Na⁺ channel inhibitors is hyperkalemia, which can be life-threatening. Consequently, amiloride and triamterene are contraindicated in patients with hyperkalemia, as well as in patients at increased risk of developing hyperkalemia (e.g., patients with renal failure, patients receiving other K⁺-sparking diuretics, patients taking angiotensin-converting enzyme inhibitors, or patients taking K⁺ supplements). Even NSAIDs can increase the likelihood of hyperkalemia in patients receiving Na⁺ channel inhibitors. Routine monitoring of the serum K⁺ level is essential in patients receiving K⁺-sparking diuretics. Cirrhotic patients are prone to megaloblastosis because of folic acid deficiency, and triamterene, a weak folic acid antagonist, may increase the likelihood of this adverse event. Triamterene also can reduce glucose tolerance and induce photosensitization and has been associated with interstitial nephritis and renal stones. Both drugs can cause CNS, GI, musculoskeletal, dermatological, and hematological adverse effects. The most common adverse effects of amiloride are nausea, vomiting, diarrhea, and headache; those of triamterene are nausea, vomiting, leg cramps, and dizziness.

**Antagonists of Mineralocorticoid Receptors: Aldosterone Antagonists, K⁺-Sparing Diuretics**

Mineralocorticoids cause salt and water retention and increase K⁺ and H⁺ excretion by binding to specific MRs. Two MR antagonists are available in the U.S., spironolactone and eplerenone (Table 25–7).

**Mechanism and Site of Action**

Epithelial cells in late distal tubule and collecting duct (particularly cortical collecting tubule) contain cytosolic MRs with high aldosterone affinity. When aldosterone binds to MRs, the MR-aldosterone complex translates to the nucleus, where it regulates the expression of multiple gene products called aldosterone-induced proteins (AIPs). Two MR antagonists are available in the U.S., spironolactone and eplerenone (Table 25–7).

Figure 25–6  Effects of aldosterone on late distal tubule and collecting duct and diuretic mechanism of aldosterone antagonists.

**A. Overview of aldosterone's influences on Na+ retention.** Via interaction with the mineralocorticoid receptor (MR), aldosterone affects myriad renal pathways that handle Na+. Key to numbered items influenced by ALDO:

1. Activation of membrane-bound Na+ channels
2. Na+ channel (ENaC) removal from the membrane inhibited
3. De novo synthesis of Na+ channels
4. Activation of membrane-bound Na+,K+-ATPase
5. Redistribution of Na+,K+-ATPase from cytosol to membrane
6. De novo synthesis of Na+,K+-ATPase
7. Changes in permeability of tight junctions
8. Increased mitochondrial production of ATP

Cortisol also has affinity for the mineralocorticoid receptor but is inactivated in the cell by 11-β-hydroxysteroid dehydrogenase (HSD) type II.

**B. Details of aldosterone's influences on membrane ENaC.** ERK signaling phosphorylates components of ENaC, making them susceptible to interaction with Nedd4-2, a ubiquitin-protein ligase that ubiquitinates ENaC, leading to its degradation. The Nedd4-2 interaction with ENaC occurs via several proline-tyrosine-proline (PY) motifs of ENaC. ALDO enhances expression of the serum and glucocorticoid-regulated kinase-1 (SGK1) and the glucocorticoid-induced leucine zipper protein (GILZ), stabilizes SGK1, enhancing its effects, and decreases ERK signaling and ENaC phosphorylation, events that prime ENaC for degradation; these effects all lead to less ubiquitination and more active ENaC in the cell membranes of the distal tubule and collecting duct. For details see Ronzaud and Staub (2014) and Ronchetti et al. (2015).

Abbreviations: AIP, aldosterone-induced proteins; ALDO, aldosterone; CH, ion channel; BL, basolateral membrane; LM, luminal membrane; MR, mineralocorticoid receptor.

**Effects on Urinary Excretion**

The effects of MR antagonists on urinary excretion are similar to those induced by renal ENaC inhibitors. However, unlike Na+ channel inhibitors, the clinical efficacy of MR antagonists is a function of endogenous aldosterone levels. The higher the endogenous aldosterone level, the greater the effects of MR antagonists on urinary excretion. MR antagonists have little or no effect on renal hemodynamics and do not alter TGF.

**Other Actions**

Spironolactone has some affinity toward progesterone and androgen receptors and thereby induces side effects such as gynecomastia, impotence, and menstrual irregularities. Owing to its 9,11-epoxide group, eplerenone has very low affinity for progesterone and androgen receptors (<1% and <0.1%, respectively) compared with spironolactone. High spironolactone concentrations can interfere with steroid biosynthesis by inhibiting steroid hydroxylases, but these effects have limited clinical relevance.

**ADME**

Spironolactone is absorbed partially (~65%), is metabolized extensively (even during its first passage through the liver), undergoes enterohepatic recirculation, and is highly protein bound. Although spironolactone per se has a short $t_{1/2}$ (~1.6 h), it is metabolized to a number of active compounds (including canrenoic acid) and it is only 10% absorbed by the body. The $t_{1/2}$ of spironolactone is prolonged to 9 h in patients with cirrhosis. Eplerenone has good oral availability and is eliminated primarily by metabolism by CYP3A4 to inactive metabolites, with a $t_{1/2}$ of about 5 h. Canrenoic acid is not active but is converted to canrenoic acid.
Mechanism and Site of Action

The IMCD is the final site along the nephron where Na⁺ is reabsorbed. Up to 5% of the filtered Na⁺ load can be reabsorbed here. The effects of nesiritide and other NPs are mediated via effects of cGMP on Na⁺ transporters (Figure 25–7). Two types of Na⁺ channels are expressed in IMCD. The first is a high conductance, 28-pS, nonselective, CNGC. This channel is inhibited by intracellular cGMP and by NPs via their capacity to stimulate membrane-bound guanylyl cyclase activity and elevate cellular cGMP. The second type of Na⁺ channel expressed in the IMCD is the low-conductance, 4-pS, highly selective Na⁺ channel ENaC. The majority of Na⁺ reabsorption in the IMCD is mediated via CNGC.

Effects on Urinary Excretion and Renal Hemodynamics

Nesiritide inhibits Na⁺ transport in both the proximal and distal nephron but its primary effect is in the IMCD. Urinary Na⁺ excretion increases with nesiritide, but the effect may be attenuated by upregulation of Na⁺ reabsorption in upstream segments of the nephron. GFR increases in response to nesiritide in normal subjects, but in treated patients with CHF, GFR may increase, decrease, or remain unchanged.

Other Actions

Administration of nesiritide decreases systemic and pulmonary resistances and left ventricular filling pressure and induces a secondary increase in cardiac output.

ADME

Natriuretic peptides are administered intravenously. Nesiritide has a distribution t½ of 2 min and a mean terminal t½ of 18 min. Clearance occurs via at least two mechanisms: internalization and subsequent degradation mediated by NPRC, and metabolism by extracellular proteases (Potter, 2011). There is no need to adjust the dose for renal insufficiency.

Therapeutic Uses

Human recombinant ANP (carperitide, available only in Japan) and BNP (nesiritide) are the available therapeutic agents of this class. Urodiłat (aluridłat) is in development. Nesiritide is indicated for the management of acutely decompensated CHF. In patients who have dyspnea with minimal activity or at rest, nesiritide reduces pulmonary capillary wedge pressure and improves short-term symptoms of dyspnea. However, the ASCEND-HF trial found that nesiritide does not change mortality and mortality in patients with heart failure with reduced ejection fraction (see Chapter 29) (D’Elia and Krum, 2014).

The MR antagonists may reduce mortality in patients with systolic dysfunction following a myocardial infarction if treated within 3 to 6 days (Roush et al., 2014). In patients with diastolic dysfunction with preserved ejection fraction, the use of MR antagonists is controversial. In such patients, MR antagonists improve left ventricular end-diastolic filling, left ventricular remodeling, and neurohumoral activation but do not improve maximal exercise capacity, quality of life, mortality, or hospitalization for heart failure (Edelmann et al., 2013; Pitt et al., 2014). MR antagonists also may reduce ventricular arrhythmias and sudden cardiac death.

The MR antagonists reduce proteinuria in patients with chronic kidney disease, and the use of these drugs in kidney diseases is under intense investigation (Bauersachs et al., 2015). Spironolactone, but not eplerenone, is widely considered to be an antiandrogenic compound and has been used to treat hirsutism and acne; however, evidence for efficacy is weak (Brown et al., 2009), and these uses are not FDA-approved. Biochemical studies suggested that spironolactone is a partial agonist of androgen receptors (Nirde et al., 2001) and can exert antiandrogen or androgenic effects depending on context (e.g., the prevailing levels of endogenous androgenic steroids). Indeed, a recent case report described spironolactone-induced worsening of prostate cancer attributed to androgen receptor stimulation (Sundar and Dickinson, 2012).

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Hyperkalemia is the principal risk of MR antagonists. Therefore, these drugs are contraindicated in patients with hyperkalemia and in those at increased risk of developing hyperkalemia. MR antagonists also can induce metabolic acidosis in cirrhotic patients. Salicylates may reduce the tubular secretion of canrenone and decrease diuretic efficacy of spironolactone. Spironolactone may alter the clearance of cardiac glycosides. Owing to its affinity for other steroid receptors, spironolactone may cause gynecomastia, impotence, decreased libido, and menstrual irregularities. Spironolactone also may induce diarrhea, gastritis, gastric bleeding, and peptic ulcers (the drug is contraindicated in patients with peptic ulcers). CNS adverse effects include drowsiness, lethargy, ataxia, confusion, and headache. Spironolactone may cause skin rashes and, rarely, blood dyscrasias. Strong inhibitors of CYP3A4 may increase plasma levels of eplerenone, and such drugs should not be administered to patients taking eplerenone and vice versa. Other than hyperkalemia and GI disorders, the rate of adverse events for eplerenone is similar to that of placebo.

Inhibitors of the Nonspecific Cation Channel: Natriuretic Peptides

Four NPs are relevant with respect to human physiology: ANP, BNP, CNP, and urodilat. The IMCD is a major site of action of NPs.

Three NPs—ANP, BNP, and CNP—share a common homologous 17-member amino acid ring formed by a disulfide bridge between cysteine residues, although they are products of different genes. Urodilat, also structurally similar, arises from altered processing of the same precursor molecule as ANP and has four additional amino acids at the N terminus. ANP and BNP are produced by the heart in response to wall stretch, CNP is of endothelial and renal cell origin; urodilat is found in the kidney and urine. NPRs, classified as types A, B, and C, are membrane monospans. NPRA (binds ANP and BNP) and NPRB (binds CNP) have intracellular domains and may help as the endogenous peptide produced by the ventricular myocardium, and subsequently CNP. NPRA (binds ANP and BNP) and NPRB (binds CNP) have intracellular domains and may help as the endogenous peptide produced by the ventricular myocardium, and subsequently CNP. NPRB (binds CNP) has a truncated intracellular domain and may help as the endogenous peptide produced by the ventricular myocardium, and subsequently CNP.
rightward shift of renal pressure natriuresis curve. Increased distribution of ECFV to venous circulation (e.g., right-sided heart failure) leading to venous congestion. Increased MABP resulting from “sensed” ECFV on the arterial side of the heart. Excessive dietary Na+. Increased distribution of ECFV to peritoneal cavity (e.g., liver cirrhosis with increased hepatic sinusoidal hydrostatic pressure) leading to ascites formation. Increased distribution of ECFV to lungs (e.g., left-sided heart failure with increased pulmonary capillary hydrostatic pressure) leading to pulmonary edema. Peripheral edema caused by altered Starling forces causing increased distribution of ECFV to interstitial space (e.g., diminished plasma proteins in nephrotic syndrome, severe burns, and liver disease). Increased MABP resulting from “Sensed” ECFV on the arterial side of the heart. These perturbations leading to edema can be addressed by: A. Correcting the underlying disease; B. Administering diuretics to left-shift the renal pressure-natriuresis relationship; C. Restricting dietary Na+ intake.

Clinical Use of Diuretics
Site and Mechanism of Diuretic Action
An understanding of the sites and mechanisms of action of diuretics enhances comprehension of the clinical aspects of diuretic pharmacology. Figure 25–5 provides a summary view of the sites and mechanisms of actions of diuretics.

The Role of Diuretics in Clinical Medicine
Figure 25–8 illustrates interrelationships among renal function, Na+ intake, water homeostasis, distribution of extracellular fluid volume, and
mean arterial blood pressure and suggests three fundamental strategies for mobilizing edema fluid:

- Correction of the underlying disease
- Restriction of Na+ intake
- Administration of diuretics

Figure 25–9 presents a useful synthesis, Brater’s algorithm, a logically compelling algorithm for diuretic therapy (specific recommendations for drug, dose, route, and drug combinations) in patients with edema caused by renal, hepatic, or cardiac disorders (Brater, 1998).

The clinical situation dictates whether a patient should receive diuretics and what therapeutic regimen should be used (type of diuretic, dose, route of administration, and speed of mobilization of edema fluid). Massive pulmonary edema in patients with acute left-sided heart failure is a medical emergency requiring rapid, aggressive therapy, including intravenous administration of a loop diuretic. In this setting, use of oral diuretics is inappropriate. Conversely, mild pulmonary and venous congestion associated with chronic heart failure is best treated with an oral loop or thiazide diuretic, the dosage of which should be titrated carefully to maximize the benefit-to-risk ratio. Loop and thiazide diuretics decrease morbidity and mortality in patients with heart failure (Faris et al., 2002); MR antagonists also demonstrate reduced morbidity and mortality in patients with heart failure receiving optimal therapy with other drugs (Roush et al., 2014).

Periodic administration of diuretics to cirrhotic patients with ascites may eliminate the necessity for or reduce the interval between paracenteses, adding to patient comfort and sparing protein reserves that are lost during paracenteses. Although diuretics can reduce edema associated with chronic renal failure, increased doses of more powerful loop diuretics usually are required. In nephrotic syndrome, diuretic response often is disappointing. In chronic renal failure and cirrhosis, edema will not pose a near-maximal effect. Ceiling doses of loop diuretics and dosing regimens for continuous intravenous infusions of loop diuretics are disease-state specific. Doses are for adults only.

Diuretic resistance refers to edema that is or has become refractory to a given diuretic. If diuretic resistance develops against a less-efficacious diuretic, a more efficacious diuretic should be substituted, such as a loop diuretic for a thiazide. However, resistance to loop diuretics can be due to several causes. NSAID coadministration is a common preventable cause of diuretic resistance. PG production, especially PGE2, is an important counterregulatory mechanism in states of reduced renal perfusion such as volume contraction, CHF, and cirrhosis characterized by activation of the RAAS and sympathetic nervous system. NSAID administration can block PG-mediated effects that counterbalance the RAAS and sympathetic nervous system, resulting in salt and water retention. Diuretic resistance also occurs with COX–2–selective inhibitors.

In chronic renal failure, a reduction in RBF decreases delivery of diuretics to the kidney, and accumulation of endogenous organic acids competes with diuretics for transport at the proximal tubule. Consequently, diuretic concentration at the active site in the tubular lumen is diminished. In nephrotic syndrome, binding of diuretics to luminal albumin was postulated to limit response; however, the validity of this concept has been challenged. In hepatic cirrhosis, nephrotic syndrome, and heart failure, nephrons may have diminished diuretic responsiveness because of increased proximal tubular Na+ reabsorption, leading to diminished Na+ delivery to distal nephrons.

Faced with resistance to loop diuretics, the clinician has several options:

- Bed rest may restore drug responsiveness by improving the renal circulation.
- An increase in dose of loop diuretic may restore responsiveness; however, nothing is gained by increasing the dose above that which causes a near-maximal effect (the ceiling dose) of the diuretic.
- Administration of smaller doses more frequently or a continuous intravenous infusion of a loop diuretic will increase the length of time that an effective diuretic concentration is at the active site.
- Use of combination therapy to sequentially block more than one site in the nephron may result in a synergistic interaction between two diuretics. For example, a combination of a loop diuretic with a K+-sparing or a
thiazide diuretic may improve therapeutic response; however, nothing is gained by the administration of two drugs of the same type. Thiazide diuretics with significant proximal tubular effects (e.g., metolazone) are particularly well suited for sequential blockade when coadministered with a loop diuretic.

- Reducing salt intake will diminish postdiuretic Na⁺ retention, which can nullify previous increases in Na⁺ excretion.
- Scheduling of diuretic administration shortly before food intake will provide effective diuretic concentration in the tubular lumen when salt load is highest.

### Part II: Water Homeostasis and the Vasopressin System

#### Vasopressin Physiology

Arginine vasopressin (ADH in humans) is the main hormone that regulates body fluid osmolality. The hormone is released by the posterior pituitary whenever water deprivation causes an increased plasma osmolality or whenever the cardiovascular system is challenged by hypovolemia or hypotension. Vasopressin acts primarily in the renal collecting duct to increase the permeability of the cell membrane to water, thus permitting water to move passively down an osmotic gradient across the collecting duct into the extracellular compartment.

Vasopressin is a potent vasopressor/vasoconstrictor. It is also a neurotransmitter; among its actions in the CNS are apparent roles in the secretion of ACTH and in regulation of the cardiovascular system, temperature, and other visceral functions. Vasopressin also promotes release of coagulation factors by vascular endothelium and increases platelet aggregability.

#### Anatomy of the Vasopressin System

The antidiuretic mechanism in mammals involves two anatomical components: a CNS component for synthesis, transport, storage, and release of vasopressin and a renal collecting duct system composed of epithelial cells that respond to vasopressin by increasing their water permeability. The CNS component of the antidiuretic mechanism is called the hypothalamoneurohypophysial system and consists of neurosecretory neurons with perikarya located predominantly in two specific hypothalamic nuclei, the SON and PVN. Long axons of magnocellular neurons in SON and PVN terminate in the neural lobe of the posterior pituitary (neurohypophysis), where they release vasopressin and oxytocin (see Figure 42–1).

#### Synthesis of Vasopressin

Vasopressin and oxytocin are synthesized mainly in the perikarya of magnocellular neurons in the SON and PVN. However, parvocellular neurons in the PVN also synthesize vasopressin, as do some non-CNS cells (see discussion that follows). Vasopressin synthesis appears to be regulated solely at the transcriptional level. In humans, a 168-amino acid preprohormone (Figure 25–10) is synthesized and then packaged into membrane-associated granules. The prohormone contains three domains: vasopressin (residues 1–9), vasopressin-neurophysin (residues 13–105), and vasopressin-glycopeptide (residues 107–145). The vasopressin domain is linked to the vasopressin-neurophysin domain through a GLY-lys-arg-processing signal, and the vasopressin-neurophysin is linked to the vasopressin-glycopeptide domain by an ARG-processing signal. In secretory granules, an endopeptidase, exopeptidase, monoxygenase, and lyase act sequentially on the prohormone to produce vasopressin, vasopressin-neurophysin (sometimes referred to as neurophysin II), and vasopressin-glycopeptide. The synthesis and transport of vasopressin depend on the preprohormone conformation. In particular, vasopressin-neurophysin binds vasopressin and is critical for correct processing, transport, and storage of vasopressin. Genetic mutations in either the signal peptide or vasopressin-neurophysin give rise to central DI.

Vasopressin also is synthesized by the heart and adrenal gland. In the heart, elevated wall stress increases vasopressin synthesis several-fold and may contribute to impaired ventricular relaxation and coronary vasconstriction. Vasopressin synthesis in the adrenal medulla stimulates catecholamine secretion from chromaffin cells and may promote adrenal cortical growth and stimulate aldosterone synthesis.

#### Regulation of Vasopressin Secretion

**Hyperosmolality.** An increase in plasma osmolality is the principal physiological stimulus for vasopressin secretion by the posterior pituitary. The osmolality threshold for secretion is about 280 mOsm/kg. Below the

---

![Figure 25–10 Processing of human AVP preprohormone. More than 40 mutations in the single gene on chromosome 20 that encodes AVP preprohormone give rise to central DI. *Boxes indicate mutations leading to central DI.*](image-url)
threshold, vasopressin is barely detectable in plasma, and above the threshold, vasopressin levels are a steep and relatively linear function of plasma osmolality. Indeed, a 2% elevation in plasma osmolality causes a 2- to 3-fold increase in plasma vasopressin levels, which in turn causes increased solute-free water reabsorption, with an increase in urine osmolality. Increases in plasma osmolality above 290 mOsm/kg lead to an intense desire for water (thirst). Thus, the vasopressin system affords the organism longer thirst-free periods and, in the event that water is unavailable, allows the organism to survive longer periods of water deprivation. Above a plasma osmolality of approximately 290 mOsm/kg, plasma vasopressin levels exceed 5 pM. Since urinary concentration is maximal (∼1200 mOsm/kg) when vasopressin levels exceed 5 pM, further defense against hypertonicity depends entirely on water intake rather than on decreases in water loss.

**Hepatic Portal Osmoreceptors.** An oral salt load activates hepatic portal osmoreceptors, leading to increased vasopressin release. This mechanism augments plasma vasopressin levels even before the oral salt load increases plasma osmolality.

**Hypovolemia and Hypotension.** Vasopressin secretion is regulated hemodynamically by changes in effective blood volume or arterial blood pressure. Regardless of the cause (e.g., hemorrhage, Na+ depletion, diuretics, heart failure, hepatic cirrhosis with ascites, adrenal insufficiency, or hypotensive drugs), reductions in effective blood volume or arterial blood pressure are associated with high circulating vasopressin concentrations. However, unlike osmoregulation, hemodynamic regulation of vasopressin secretion is exponential; that is, small decreases (5%) in blood volume or pressure have little effect on vasopressin secretion, whereas larger decreases (20%-30%) can increase vasopressin levels to 20–30 times normal (exceeding the vasopressin concentration required to induce maximal antidiuresis). Vasopressin is one of the most potent vasoconstrictors known, and the vasopressin response to hypovolemia or hypotension serves as a mechanism to stave off cardiovascular collapse during periods of severe blood loss or hypotension. Hemodynamic regulation of vasopressin secretion does not disrupt osmotic regulation; rather, hypovolemia/hypotension alters the set point and slope of the plasma osmolality-plasma vasopressin relationship.

Neuronal pathways that mediate hemodynamic regulation of vasopressin release are different from those involved in osmoregulation. Baroreceptors in the left atrium, left ventricle, and pulmonary veins sense blood volume (filling pressures), and baroreceptors in the carotid sinus and aorta monitor arterial blood pressure. Nerve impulses reach brainstem nuclei predominantly through the vagal trunk and glossopharyngeal nerve; these signals are ultimately relayed to the SON and PVN.

**Hormones and Neurotransmitters.** Vasopressin-synthesizing magnocellular neurons have a large array of receptors on both perikarya and nerve terminals; therefore, vasopressin release can be accentuated or attenuated by chemical agents acting at both ends of the magnocellular neuron (Iovino et al., 2014). Also, hormones and neurotransmitters can modulate vasopressin secretion by stimulating or inhibiting neurons in nuclei that project, either directly or indirectly, to the SON and PVN (Iovino et al., 2014). Because of these complexities, modulation of vasopressin secretion by most hormones or neurotransmitters is unclear. Several agents stimulate vasopressin secretion, including acetylcholine (by nictinic receptors), histamine (by H1 receptors), dopamine (by both D1 and D2 receptors), glutamine, aspartate, cholecystokinin, neuropeptide Y, substance P, vasoactive intestinal polypeptide, PGs, and AngII. Inhibitors of vasopressin secretion include ANF, γ-aminobutyric acid, and opioids (particularly dynorphin via κ receptors). The effects of AngII have received the most attention. AngII synthesized in the brain and circulating AngII may stimulate vasopressin release. Inhibition of the conversion of AngII to AngIII blocks AngII-induced vasopressin release, suggesting that AngIII is the main effector peptide of the brain renin-angiotensin system controlling vasopressin release.

**Pharmacological Agents.** A number of drugs alter urine osmolality by stimulating or inhibiting vasopressin secretion. In most cases, the mechanism is not known. Stimulators of vasopressin secretion include vinceristine, cyclophosphamide, tricyclic antidepressants, nicotine, epinephrine, and high doses of morphine. Lithium, which inhibits the renal effects of vasopressin, also enhances vasopressin secretion. Inhibitors of vasopressin secretion include ethanol, phenytoin, low doses of morphine, glucocorticoids, fluphenazine, haloperidol, promethazine, oxilorphan, and butorphanol. Carbamazepine has a renal action to produce antidiuresis in patients with central DI but actually inhibits vasopressin secretion by a central action. Ethanol inhibits vasopressin secretion (see Chapter 23).

**Vasopressin Receptors**

Cellular vasopressin effects are mediated mainly by interactions of the hormone with the three types of receptors: V1A, V1B, and V2. All are GPCRs. The V1A receptor is the most widespread subtype of vasopressin receptor; it is found in vascular smooth muscle, adrenal gland, myometrium, bladder, adipocytes, hepatocytes, platelets, renal medullary interstitial cells, vasa recta in the renal microcirculation, epithelial cells in the renal cortical collecting duct, spleen, testis, and many CNS structures. V1A receptors have a more limited distribution and are found in the anterior pituitary, several brain regions, pancreas, and adrenal medulla. V1B receptors are located predominantly in principal cells of the renal collecting duct system but also present on atrial cells in TAL and on vascular endothelial cells.

Figure 25–11 summarizes the current model of V1A receptor-effector coupling. Vasopressin binding to V1A receptors activates the G-PLC-IP3 pathway, thereby mobilizing intracellular Ca2+ and activating PKC, ultimately causing biological effects that include immediate responses (e.g., vasoconstriction, glycogenolysis, platelet aggregation, and ACTH release) and growth responses in smooth muscle cells.

Principal cells in the renal collecting duct have V2 receptors on their basolateral membranes that couple to Gq to stimulate adenylyl cyclase activity (Figure 25–12). The resulting activation of the cyclic AMP/PKA pathway triggers an increased rate of insertion of water channel-containing vesicles (WCVs) into the apical membrane and a decreased rate of endocytosis of WCVs from the apical membrane. Because WCVs contain preformed functional water channels (aquaporin 2), their net shift into apical membranes in response to V2 receptor stimulation greatly increases water permeability of the apical membrane (Nejsum, 2005) (see Figures 25–12 and 25–13).

V1B receptor activation also increases urea permeability by 400% in the terminal portions of the IMCD. V1B receptors increase urea permeability by activating a vasopressin-regulated urea transporter (termed URA1, UT1, or UT4A), most likely by PKA-induced phosphorylation. Kinetics of vasopressin-induced water and urea permeability differ, and vasopressin-induced regulation of VRUT does not entail vesicular trafficking to the plasma membrane.

V2 receptor activation also increases Na+ transport in TAL and collecting duct. Increased Na+ transport in TAL is mediated by three mechanisms that affect the Na+-K–2Cl– symporter: rapid phosphorylation of the symporter, translocation of the symporter into the luminal membrane, and increased expression of symporter protein. The multiple mechanisms by which vasopressin increases water reabsorption are summarized in Figure 25–14.

**Renal Actions of Vasopressin**

Several sites of vasopressin action in kidney involve both V1A and V2 receptors. V1A receptors mediate contraction of mesangial cells in the glomerulus and contraction of vascular smooth muscle cells in vasa recta and efferent arterioles. V2 receptor-mediated reduction of inner medullary blood flow contributes to the maximum concentrating capacity of the kidney. V2 receptors also stimulate PG synthesis by medullary interstitial cells. Because PGE2 inhibits adenylyl cyclase in collecting ducts, stimulation of PG synthesis by V2 receptors may counterbalance V2 receptor-mediated antidiuresis. V2 receptors on principal cells in cortical collecting ducts may inhibit V2 receptor-mediated water flux by activation of PKC. V2 receptors mediate the most prominent response to vasopressin, which is increased water permeability of the collecting duct at concentrations as low as 50 fM. Thus, V2 receptor-mediated effects of vasopressin occur at concentrations far lower than are required to engage...
Figure 25–11  Mechanism of V1 receptor-effector coupling. Binding of AVP to V1 vasopressin receptors (V1) stimulates membrane-bound phospholipases. Stimulation of Gα activates the PLCβ/IP3/DAG-Ca2+-PKC pathway. Activation of V1 receptors also causes influx of extracellular Ca2+ by an unknown mechanism. PKC and Ca2+/calmodulin-activated protein kinases phosphorylate cell-type–specific proteins, leading to cellular responses. A further component of the AVP response derives from the production of eicosanoids secondary to the activation of PLA2; the resulting mobilization of AA provides substrate for eicosanoid synthesis by the COX and LOX pathways, leading to local production of PGs, TXs, and LT, which may activate myriad signaling pathways, including those linked to Gαq, Gαs, and Gα12/13.

V1 receptor–mediated actions. Other renal actions mediated by V1 receptors include increased urea transport in the IMCD and increased Na+ transport in the TAL; both effects contribute to the urine-concentrating ability of the kidney. V1 receptors also increase Na+ transport in cortical collecting ducts, and this may synergize with aldosterone to enhance Na+ reabsorption during hypovolemia.

Pharmacological Modification of the Antidiuretic Response to Vasopressin

The NSAIDs, particularly indomethacin, enhance the antidiuretic response to vasopressin. Because PGs attenuate antidiuretic responses to vasopressin and NSAIDs inhibit PG synthesis, reduced PG production probably accounts for potentiation of vasopressin’s antidiuretic response. Carbamazepine and chlorpropamide also enhance antidiuretic effects of vasopressin by unknown mechanisms. In rare instances, chlorpropamide can induce water intoxication. A number of drugs inhibit the antidiuretic actions of vasopressin. Lithium is of particular importance because of its use in the treatment of manic-depressive disorders (Kishore and Ecelbarger, 2013). Acutely, Li+ appears to reduce V1 receptor–mediated stimulation of adenylyl cyclase. Also, Li+ increases plasma levels of PTH, a partial antagonist to vasopressin. In most patients, the antibiotic demeclocycline attenuates the antidiuretic effects of vasopressin, probably owing to decreased accumulation and action of cyclic AMP (Kortenoeven et al., 2013).

Nonrenal Actions of Vasopressin

Cardiovascular System. The cardiovascular effects of vasopressin are complex. Vasopressin is a potent vasoconstrictor (V1 receptor mediated), and resistance vessels throughout the circulation may be affected. Vascular smooth muscle in the skin, skeletal muscle, fat, pancreas, and thyroid gland appears most sensitive, with significant vasoconstriction also occurring in the GI tract, coronary vessels, and brain. Despite the potency of vasopressin as a direct vasoconstrictor, vasopressin-induced pressor responses in vivo are minimal and occur only with vasopressin concentrations significantly higher than those required for maximal antidiuresis. To a large extent, this is due to circulating vasopressin actions on V1 receptors to inhibit sympathetic efferents and potentiate baroreflexes. In addition, V1 receptors cause vasodilation in some blood vessels.

Vasopressin helps to maintain arterial blood pressure during episodes of severe hypovolemia/hypotension. The effects of vasopressin on the heart (reduced cardiac output and heart rate) are largely indirect and result from coronary vasoconstriction, decreased coronary blood flow, and alterations (reduced cardiac output and heart rate) are largely indirect and result from coronary vasoconstriction, decreased coronary blood flow, and alterations in vagal and sympathetic tone. Some patients with coronary insufficiency experience angina even in response to the relatively small amounts of vasopressin required to control DI, and vasopressin-induced myocardial ischemia has led to severe reactions and even death.

CNS. Vasopressin likely plays a role as a neurotransmitter or neuromodulator. Although vasopressin can modulate CNS autonomic systems controlling heart rate, arterial blood pressure, respiration rate, and sleep patterns, the physiological significance of these actions is unclear. While vasopressin is not the principal corticotropin-releasing factor, vasopressin may provide for sustained activation of the hypothalamic–pituitary–adrenal axis during chronic stress. Studies in both laboratory animals and humans indicated that vasopressin and oxytocin are key regulators of social and emotional behaviors (Benarroch, 2013). CNS effects of vasopressin appear to be mediated predominantly by V1 receptors.

Blood Coagulation. Activation of V1 receptors by desmopressin or vasopressin increases circulating levels of procoagulant factor VIII and of von Willebrand factor. These effects are mediated by extrarenal V1 receptors. Presumably, vasopressin stimulates secretion of von Willebrand factor and of factor VIII from storage sites in vascular endothelium. However, because release of von Willebrand factor does not occur when desmopressin is applied directly to cultured endothelial cells or to isolated blood vessels, intermediate factors are likely to be involved.
to the V2 receptor activates the Gs-adenyl cyclase-cAMP-PKA pathway and phosphorylates the principal cell of the collecting duct, thus enhancing water permeability. Although phosphorylation of Ser256 of aquaporin 2 is involved in V2 receptor signaling, other proteins located in both the water channel–containing vesicles and the apical membrane of the cytoplasm also may be involved.

**Other Nonrenal Effects.** At high concentrations, vasopressin stimulates smooth muscle contraction in the uterus (by oxytocin receptors) and GI tract (by V1 receptors). Vasopressin is stored in platelets, and activation of V1 receptors stimulates platelet aggregation. Also, activation of V1 receptors on hepatocytes stimulates glycogenolysis.

**Vasopressin Receptor Agonists**

A number of vasopressin-like peptides occur naturally across the animal kingdom (Table 25–8); all are nonapeptides. In all mammals except swine, the neurohypophyseal peptide is 8-arginine vasopressin, and the terms vasopressin, AVP, and ADH are used interchangeably. There are also a number of synthetic peptides with receptor-subtype specificity, and one nonpeptide agonist.

Many vasopressin analogues were synthesized with the goal of increasing duration of action and selectivity for vasopressin receptor subtypes (V1 vs. V2 receptors, which mediate pressor responses and antidiuretic responses, respectively). Thus, the antidiuretic-to-vasopressor ratio for the V2–selective agonist, DDAVP, also called desmopressin, is about 3000 times greater than that for vasopressin. Increasing V1 selectivity has proved more difficult than increasing V2 selectivity. Vasopressin receptors in the adenohypophysis that mediate vasopressin-induced ACTH release are neither classical V1 nor V2 receptors. Because vasopressin receptors in the adenohypophysis appear to share a common signal-transduction mechanism with classical V1 receptors, and because many vasopressin analogues with vasoconstrictor activity release ACTH, V1 receptors have been subclassified into V1a (vascular/hepatic) and V1b (pituitary) receptors (also called V3 receptors). There are selective agonists for V1a and V1b receptors.

The chemical structure of oxytocin is closely related to that of vasopressin: Oxytocin is [Ile3, Leu8]AVP. With such structural similarities, it is not surprising that vasopressin and oxytocin agonists and antagonists can bind to each other's receptors. Therefore, most of the available peptide vasopressin agonists and antagonists have some affinity for oxytocin receptors; at high doses, they may block or mimic the effects of oxytocin.

**Diseases Affecting the Vasopressin System**

**Diabetes Insipidus**

Diabetes insipidus is a disease of impaired renal water conservation owing either to inadequate vasopressin secretion from the neurohypophysis...

*Available for clinical use.

**Figure 25–14** Mechanisms by which vasopressin increases the renal conservation of water. Red and black arrows denote major and minor pathways, respectively.
466 circulating vasopressin and will reduce urine volume in more than half of all patients with central DI. Doses of 125–500 mg daily appear effective in patients with partial central DI. If polyuria is not controlled satisfactorily with chlorpropamide alone, addition of a thiazide diuretic to the regimen usually results in an adequate reduction in urine volume. Carbamazepine (800–1000 mg daily in divided doses) also reduces urine volume in patients with central DI. Long-term use may induce serious adverse effects; therefore, carbamazepine is used rarely to treat central DI. These agents are not effective in nephrogenic DI, which indicates that functional V₁ receptors are required for the antidiuretic effect. Because carbonic anhydrase inhibits and chlorpropamide has little effect on vasopressin secretion, it is likely that carbamazepine and chlorpropamide act directly on the kidney to enhance V₂ receptor–mediated antidiuresis.

**Nephrogenic DI.** Nephrogenic DI may be congenital or acquired. Hypercalcemia, hypokalemia, postobstructive renal failure, Li⁺, foscarnet, clozapine, demeclocycline, and other drugs can induce nephrogenic DI. As many as one in three patients treated with Li⁺ may develop nephrogenic DI. X-linked nephrogenic DI is caused by mutations in the gene encoding the V₂ receptor, which maps to Xq28. Mutations in the V₂ receptor gene may cause impaired routing of the V₂ receptor to the cell surface, defective coupling of the receptor to G proteins, or decreased receptor affinity for vasopressin. Autosomal recessive and dominant nephrogenic DI result from inactivating mutations in aquaporin 2. These findings indicate that aquaporin 2 is essential for the antidiuretic effect of vasopressin in humans.

Although the mainstay of treatment of nephrogenic DI is assurance of an adequate water intake, drugs also can be used to reduce polyuria. Amiloride blocks Li⁺ uptake by the Na⁺ channel in the collecting duct system and may be effective in patients with mild-to-moderate concentrating defects. Thiazide diuretics reduce the polyuria of patients with DI and often are used to treat nephrogenic DI. In infants with nephrogenic DI, use of thiazides may be crucial because uncontrolled polyuria may exceed the child’s capacity to imbibe and absorb fluids. It is possible that the natriuretic action of thiazides and resulting extracellular fluid volume depletion play an important role in thiazide-induced antidiuresis. The antidiuretic effects appear to parallel the thiazide’s ability to cause natriuresis, and the drugs are given in doses similar to those used to mobilize edema fluid. In patients with DI, a 50% reduction of urine volume is a good response to thiazides. Moderate restriction of Na⁺ intake can enhance the antidiuretic effectiveness of thiazides.

A number of case reports described the effectiveness of indomethacin in the treatment of nephrogenic DI; however, other PG synthase inhibitors (e.g., ibuprofen) appear to be less effective. The mechanism of the effect may involve a decrease in GFR, an increase in medullary solute concentration, or enhanced proximal fluid reabsorption. Also, because PGS attenuate vasopressin-induced antidiuresis in patients with at least a partially intact V₂ receptor system, some of the antidiuretic response to indomethacin may be due to diminution of the PG effect and enhancement of vasopressin effects on the principal cells of collecting duct.

**Syndrome of Inappropriate Secretion of Antidiuretic Hormone**

A disease of impaired water excretion accompanying hyponatremia and hypoosmolality, SIADH caused by the inappropriate secretion of vasopressin. Clinical manifestations of plasma hypotonicity resulting from SIADH may include lethargy, anorexia, nausea and vomiting, muscle cramps, coma, convulsions, and death. A multitude of disorders can induce SIADH, including malignancies, pulmonary diseases, CNS injuries/diseases (e.g., head trauma, infections, and tumors), and general surgery.

Three drug classes are commonly implicated in drug-induced SIADH: psychotropic medications (e.g., selective serotonin reuptake inhibitors, haloperidol, and tricyclic antidepressants), sulfonylureas (e.g., chlorpropamide), and vinca alkaloids (e.g., vincristine and vinblastine). Other drugs strongly associated with SIADH include clonidine, cyclophosphamide, enalapril, felnamate, ifosfamide, methylxypa, pentamidine, and vinorelbine. Many other drugs have been implicated. In a normal individual, an elevation in plasma vasopressin per se does not induce plasma hypotonicity because the person simply stops drinking owing to an osmotically induced aversion to fluids. Therefore, plasma hypotonicity only occurs when excessive fluid intake (oral or intravenous) accompanies inappropriate secretion of vasopressin.

Treatment of hypotonicity in the setting of SIADH includes water restriction, intravenous administration of hypertonic saline, loop diuretics (which interfere with kidney’s concentrating ability), and drugs that inhibit the effect of vasopressin to increase water permeability in collecting ducts. To inhibit vasopressin’s action in collecting ducts, demeclocycline, a tetracycline, has been the preferred drug, but tolvaptan and conivaptan, V₂ receptor antagonists, are now available (see next section and Table 25–9).

Although Li⁺ can inhibit the renal actions of vasopressin, it is effective in only a minority of patients, may induce irreversible renal damage when used chronically, and has a low therapeutic index. Therefore, Li⁺ should be considered for use only in patients with symptomatic SIADH who cannot be controlled by other means or in whom tetracyclines are contraindicated (e.g., patients with liver disease). It is important to stress that the majority of patients with SIADH do not require therapy because plasma Na⁺ levels drop below 120 mM; such patients usually are asymptomatic. Only when symptomatic hypotonicity ensues, generally when plasma Na⁺ levels drop below 120 mM, should therapy with demeclocycline be initiated. Because hypotonicity, which causes an influx of water into cells with resulting cerebral swelling, is the cause of symptoms, the goal of therapy is simply to increase plasma osmolality toward normal.

**Other Water-Retaining States**

In patients with Cushing’s syndrome, nephrotic syndrome, effective blood volume often is reduced, and hypovolemia frequently is exacerbated by the liberal use of diuretics. Because hypovolemia stimulates vasopressin release, patients may become hyponatremic owing to vasopressin-mediated retention of water. The development of potent orally active V₁ receptor antagonists and specific inhibitors of water channels in the collecting duct has provided a new therapeutic strategy not only in patients with SIADH but also in the more common setting of hyponatremia in patients with heart failure, liver cirrhosis, and nephrotic syndrome.

**Clinical Use of Vasopressin Agonists**

Two antidiuretic peptides are available for clinical use in the U.S.:

- **Vasopressin** (synthetic 8-arginine vasopressin) is available as a sterile aqueous solution; it may be administered intravenously, subcutaneously, intramuscularly, intranasally (off label), intra-arterially, or endotracheally (off label; unreliable).
- **Desmopressin acetate** (synthetic DDAVP) is available as a sterile aqueous solution packaged for intravenous or subcutaneous injection, in a solution for intranasal administration with either a nasal spray pump or rhinal tube delivery system, and in tablets for oral administration.

**Therapeutic Uses**

The therapeutic uses of vasopressin and its congeners can be divided into two main categories according to the vasopressin receptor involved: V₁ receptor mediated and V₂ receptor mediated.

- **V₁ receptor–mediated** therapeutic applications are based on the rationale that V₁ receptors cause G1 and vascular smooth muscle contraction. **Vasopressin is the main agent used.** V₂ receptor–mediated GI smooth muscle contraction has been used to treat postoperative ileus and abdominal distension and to dispel intestinal gas before abdominal roentgenography to avoid interfering gas shadows. **V₁ receptor–mediated vasocostriction of the splanchnic arterial vessels reduces blood flow to the portal system and thereby attenuates pressure and bleeding in esophageal varices.** Although endoscopic variceal banding ligation is the treatment of choice for bleeding esophageal varices, V₁ receptor agonists have been used in an emergency setting until endoscopy can be performed. Simultaneous administration of nitroglycerin with V₁ receptor agonists may attenuate the cardiotoxic effects of V₁ agonists while enhancing their beneficial
splanchnic effects. Also, V2 receptor agonists have been used during abdominal surgery in patients with portal hypertension to diminish the risk of hemorrhage during the procedure. V1 receptor–mediated vasoconstriction has been used to reduce bleeding during acute hemorrhagic gastritis, burn wound excision, cyclophosphamide-induced hemorrhagic cystitis, liver transplant, cesarean section, and uterine myoma resection. Vasopressin levels in patients with vasodilatory shock are inappropriately low, and such patients are extraordinarily sensitive to the pressor actions of V1 receptor agonists. Therefore, V1 receptor agonists are indicated for the treatment of hypotension in patients with vasodilatory shock that responds insufficiently to therapy with fluids and catecholamines (Serpa Neto et al., 2012). Vasopressin combined with epinephrine and steroids showed improved outcomes after in-hospital cardiac arrest (Layek et al., 2014).

V2 receptor–mediated therapeutic applications are based on the rationale that V2 receptors cause water conservation and release of blood coagulation factors. Desmopressin is the standard drug of choice. Central, but not nephrogenic, DI can be treated with V2 receptor agonists, and polyuria and polydipsia usually are well controlled by these agents. Some patients experience transient DI (e.g., in head injury or surgery in the area of the pituitary); however, therapy for most patients with DI is lifelong. Desmopressin is the drug of choice for the vast majority of patients. The duration of effect from a single intranasal dose is from 6 to 20 h; twice-daily administration is effective in most patients. The usual intranasal dosage in adults is 10–40 μg daily either as a single dose or divided into two or three doses. In view of the high cost of the drug and the importance of avoiding water intoxication, the schedule of administration should be adjusted to the minimal amount required. In some patients, chronic allergic rhinitis or other nasal pathology may preclude reliable peptide absorption following nasal administration. Oral administration of desmopressin in doses of 0.1–1.2 mg/d provides adequate desmopressin blood levels to control polyuria. Subcutaneous or intravenous administration of 2–4 μg daily of desmopressin also is effective in central DI.

Vasopressin has little, if any, place in the long-term therapy of DI because of its short duration of action and V2 receptor–mediated side effects. Vasopressin can be used as an alternative to desmopressin in the initial diagnostic evaluation of patients with suspected DI and to control polyuria in patients with DI who recently have undergone surgery or experienced head trauma. Under these circumstances, polyuria may be transient and long-acting agents may produce water intoxication.

Desmopressin is used in bleeding disorders. In most patients with type I vWD and in some with type IIb vWD, desmopressin will elevate von Willebrand factor and shorten bleeding time. However, desmopressin generally is ineffective in patients with types IIa, IIb, and III vWD. Desmopressin may cause a marked transient thrombocytopenia in individuals with type IIb vWD and is contraindicated in such patients. Desmopressin also increases factor VIII levels in patients with mild-to-moderate hemophilia A. Desmopressin is not indicated in patients with severe hemophilia A, those with hemophilia B, or those with factor VIII antibodies. In patients with renal insufficiency, desmopressin shortens bleeding time and increases circulating levels of factor VIII coagulant activity, factor VIII–related antigen, and ristocetin cofactor. It also induces the appearance of larger von Willebrand factor multimers. Desmopressin is effective in some patients with liver cirrhosis- or drug-induced (e.g., heparin, hirudin, and antplatelet agents) bleeding disorders. Desmopressin, given intravenously at a dose of 0.3 μg/kg, increases factor VIII and von Willebrand factor for more than 6 h. Desmopressin can be given at intervals of 12–24 h depending on the clinical response and severity of bleeding. Tachyphylaxis to desmopressin usually occurs after several days (owing to depletion of factor VIII and von Willebrand factor storage sites) and limits its usefulness to preoperative preparation, postoperative bleeding, excessive menstrual bleeding, and emergency situations.

Another V2 receptor–mediated therapeutic application is the use of desmopressin for primary nocturnal enuresis. Bedtime administration of desmopressin tablets provides a high response rate that is sustained with long-term use and that accelerates the cure rate. Intranasal desmopressin is no longer recommended for the treatment of primary nocturnal enuresis because of increased risk of hyponatremia. Desmopressin also relieves post–lumbar puncture headache, probably by causing water retention and thereby facilitating rapid fluid equilibration in the CNS.

*Available for clinical use in United States.
CHAPTER 25

ADME

When vasopressin and desmopressin are given orally, they are inactivated quickly by trypsin. Inactivation by peptidases in various tissues (particularly liver and kidney) results in a plasma half-life of 17–35 min. Following intramuscular or subcutaneous injection, anti-diuretic effects of vasopressin last 2–8 h. The half-life of desmopressin is 75 min to 3.5 h.

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Most adverse effects are mediated through V1 receptor activation on vascular and GI smooth muscle; such adverse effects are much less common and less severe with desmopressin than with vasopressin. After injection of large doses of vasopressin, marked facial pallor owing to cutaneous vasoconstriction is observed commonly. Increased intestinal activity is likely to cause nausea, belching, cramps, and an urge to defecate. Vasopressin should be administered with extreme caution in individuals suffering from vascular disease, especially coronary artery disease. Other cardiac complications include arrhythmia and decreased cardiac output. Peripheral vasoconstriction and gangrene were encountered in patients receiving large doses of vasopressin.

The major V1 receptor–mediated adverse effect is water intoxication. Many drugs, including carbamazepine, chlorpropamide, morphine, tricyclic antidepressants, and NSAIDs, can potentiate the antidiuretic effects of these peptides. Several drugs, such as Li+, demeclocycline, and ethanol, can attenuate the antidiuretic response to desmopressin. Desmopressin and vasopressin should be used cautiously in disease states in which a rapid increase in extracellular water may impose risks (e.g., in angina, hypertension, and heart failure) and should not be used in patients with acute renal failure. Patients receiving desmopressin to maintain hemostasis should be advised to reduce fluid intake. Also, it is imperative that these peptides not be administered to patients with primary or psychogenic polydipsia because severe hypotonic hyponatremia will ensue. Mild facial flushing and headache are the most common adverse effects. Allergic reactions ranging from urticaria to anaphylaxis may occur with desmopressin or vasopressin. Intranasal administration may cause local adverse effects in the nasal passages, such as edema, rhinorrhea, congestion, irritation, pruritus, and ulceration.

Clinical Use of Vasopressin Antagonists

Table 25–9 summarizes the selectivity of vasopressin receptor antagonists. Only tolvaptan and conivaptan are currently available in the United States.

Therapeutic Uses

When the kidney perceives the arterial blood volume to be low (as in the disease states of CHF, cirrhosis, and nephrosis), AVP perpetuates a state of total body salt and water excess. V2 receptor antagonists or “aquaretics” may have a therapeutic role in these conditions, especially in patients with concomitant hyponatremia. They are also effective in hyponatremia associated with SIADH. Aquaretics increase renal free water excretion with little or no change in electrolyte excretion. Because they do not affect Na+ reabsorption, they do not stimulate the TGF mechanism with its associated consequence of reducing GFR.

Tolvaptan is a selective oral V2 receptor antagonist FDA-approved for clinically significant hypervolemic and euvolemic hyponatremia. Conivaptan is a nonselective V1/V2 receptor antagonist that is FDA-approved for the treatment of hospitalized patients with euvolemic and hypervolemic hyponatremia. Conivaptan is available only for intravenous infusion. Expert panels have yet to reach a consensus regarding the appropriate use of V2 receptor antagonists (Berl, 2015).

ADME

Tolvaptan has a half-life of 2.8–12 h and less than 1% is excreted in the urine. Tolvaptan is a substrate and inhibitor of P-glycoprotein and is eliminated entirely by CYP3A4 metabolism. Conivaptan is highly protein bound, has a terminal elimination half-life of 5–12 h, is metabolized via CYP3A4, and is partially excreted by the kidney.

Toxicity, Adverse Effects, Contraindications, Drug Interactions

The most dangerous adverse effect of V2 receptor antagonists is due to their pharmacological action to increase free water excretion. This may correct hyponatremia too rapidly, resulting in serious and even fatal consequences (osmotic demyelination syndrome). Indeed, tolvaptan is labeled with a black-box warning against too rapid correction of hyponatremia and with the recommendation to initiate therapy in a hospital setting capable of close monitoring of serum Na+. V2 receptor antagonists should not be used with hypertonic saline. Antagonism of V1 receptors can also cause polyuria, which likely explains the increased incidence of dehydration, hypotension, dizziness, pyrexia, increased thirst, and xerostomia with this class of drugs. Both tolvaptan and conivaptan can cause adverse GI effects. Tolvaptan can cause liver damage; therefore, administration of tolvaptan generally should be limited to 30 days, and tolvaptan should not be used in patients with liver disease. Both tolvaptan and conivaptan can induce headaches, hypokalemia, and hyperglycemia, and both are contraindicated in anuria (no benefit) and in patients receiving drugs that inhibit CYP3A4 (e.g., clarithromycin, ketoconazole).

The Renin-Angiotensin System

The RAS participates in the pathophysiology of hypertension, congestive heart failure, myocardial infarction, and diabetic nephropathy. This realization has led to a thorough exploration of the RAS and the development of new approaches for inhibiting its actions. This chapter discusses the physiology, biochemistry, and cellular and molecular biology of the classical RAS and novel RAS components and pathways. The chapter also discusses the basic pharmacology of drugs that interrupt the RAS, and the clinical utility of inhibitors of the RAS. Therapeutic applications of drugs covered in this chapter are also discussed in Chapters 27–29.

**History**

In 1898, Tiegerstedt and Bergman found that crude saline extracts of the kidney contained a pressor substance that they named renin. In 1934, Goldblatt and his colleagues demonstrated that constriction of the renal arteries produced persistent hypertension in dogs. In 1940, Braun-Menendez and his colleagues in Argentina and Page and Helmer in the U.S. reported that renin was an enzyme that acted on a plasma protein substrate to catalyze the formation of the actual pressor material, a peptide, that was named hypertensin by the former group and angiotonin by the latter. Ultimately, the pressor substance was renamed angiotensin, and the plasma substrate was called angiotensinogen.

In the mid-1950s, two forms of angiotensin were recognized, a decapeptide (AngI) and an octapeptide (AngII) formed by proteolytic cleavage of AngI by an enzyme termed ACE. The octapeptide was the more active form, and its synthesis in 1957 by Schwyzer and by Bumpus made the material available for intensive study. Later research showed that the kidneys are an important site of aldosterone action, and that angiotensin potently stimulates the production of aldosterone in humans. Moreover, renin secretion increased with depletion of Na+. Thus, the RAS became recognized as a mechanism to stimulate aldosterone synthesis and secretion and an important homeostatic mechanism in the regulation of blood pressure and electrolyte composition.

In the early 1970s, polypeptides were discovered that either inhibited the formation of AngII or blocked AngII receptors. These inhibitors revealed important physiological and pathophysiological roles for the RAS and inspired the development of a new and broadly efficacious class of antihypertensive drugs: the orally active ACE inhibitors. Studies with ACE inhibitors uncovered roles for the RAS in the pathophysiology of hypertension, heart failure, vascular disease, and renal failure. Selective and competitive antagonists of AngII receptors were subsequently developed that yielded losartan, the first orally active, highly selective, and potent nonpeptide AngII receptor antagonist (Dell’Italia, 2011). Subsequently, many other AngII receptor antagonists have been developed; more recently, aliskiren, a direct renin inhibitor, was approved for antihypertensive therapy.

**Classical RAS**

Through the actions of AngII, the RAS participates in blood pressure regulation, aldosterone release, Na+-reabsorption from renal tubules, electrolyte and fluid homeostasis, and cardiovascular remodeling. AngII is derived from angiotensinogen in two proteolytic steps. First, the enzyme renin, released into the circulation from the JG cells in the kidneys, cleaves the decapeptide AngI from the amino terminus of angiotensinogen (renin substrate). Then, an ACE, located on the endothelial cell lining of the vasculature, removes the carboxy-terminal dipeptide of AngI to produce the octapeptide AngII. These enzymatic steps are summarized in Figure 26–1. AngII acts by binding to two distinct heptaspanning GPCRs, AT₁, and AT₂.

**New Paradigms in the RAS**

The RAS has expanded from being solely an endocrine system to include a paracrine, autocrine/intracrine hormonal system with several new components and active pathways. The current understanding of the RAS involves local (tissue) RAS; alternative pathways for AngII synthesis (ACE independent and renin independent); an ACE2/Ang(1–7)/Mas receptor axis that opposes the vasoconstrictor effects of ACE/AngII/AT₁ receptor axis; an AT₄ receptor axis; and an AngIV/AT₄ receptor axis that is important in brain functions and cognition; multiple biologically active angiotensin peptides such Ang(1–9), AngIII, Ang(3–7), angiotensin A, and alamandine; multiple receptors for angiotensin (AT₁, AT₂, AT₄, Mas, and MrgD); and

Regulation of the macula densa pathway is more dependent on the luminal concentration of Na⁺ than NaCl. NaCl transport into the macula densa is mediated by the Na⁺-K⁺-2Cl⁻ symporter (Figure 26–4), and the half-maximal concentrations of Na⁺ and Cl⁻ required for transport via this symporter are 2–3 and 40 mEq/L, respectively. Because the luminal concentration of Na⁺ at the macula densa usually is much greater than the level required for half-maximal transport, physiological variations in luminal Na⁺ concentrations at the macula densa have little effect on renin release (i.e., the symporter remains saturated with respect to Na⁺). Conversely, physiological changes in Cl⁻ concentrations (20–60 mEq/L) at the macula densa profoundly affect macula densa–mediated renin release.

The Intrarenal Baroreceptor Pathway

Increases and decreases in blood pressure or renal perfusion pressure in the preglomerular vessels inhibit and stimulate renin release, respectively. The immediate stimulus to secretion is believed to be reduced tension within the wall of the afferent arteriole. The release of renal PGs and biochemical coupling via stretch-activated ion channels may mediate in part the intrarenal baroreceptor pathway.

The β₁ Adrenergic Receptor Pathway

The β₁ adrenergic receptor pathway is regulated by the release of NE from postganglionic sympathetic nerves; activation of β₁ receptors on JG cells increases cyclic AMP and enhances renin secretion. Treatment with β₁ blockers reduces renin secretion and PRA.

Feedback Regulation

Renin release is subject to feedback regulation (Figure 26–3). Increased renin secretion enhances the formation of AngII, which stimulates AT₁ receptors on JG cells to inhibit renin release, an effect termed short-loop negative feedback. Inhibition of renin release due to AngII–dependent increase in blood pressure is termed long-loop negative feedback. AngII increases arterial blood pressure via AT₁ receptors; this effect inhibits renin release by the following:

**Drugs That Affect Renin Secretion**

Renin release is influenced by arterial blood pressure, dietary salt intake, and pharmacological agents (Figures 26–3 and 26–4). Loop diuretics stimulate renin release and increase PRC by decreasing arterial blood pressure and by blocking the reabsorption of NaCl at the macula densa. NSAIDs inhibit PG synthesis and thereby decrease renin release. ACE inhibitors, ARBs, and renin inhibitors interrupt both the short- and long-loop negative-feedback mechanisms and therefore increase renin release and PRC. Centrally acting sympatholytic drugs, as well as β₁ adrenergic receptor antagonists, decrease renin secretion by reducing activation of β₁ adrenergic receptors on JG cells.

**Angiotensinogen**

The substrate for renin is angiotensinogen, an abundant globular glycoprotein. Ang I is cleaved by renin from the amino terminus of angiotensinogen. Human angiotensinogen contains 452 amino acids and is synthesized as proangiotensinogen, which has a 24– or 33–amino acid signal peptide. Angiotensinogen is synthesized and secreted primarily by the liver, although angiotensinogen transcripts occur in many tissues, including the heart, kidneys, pancreas, adipocytes, and certain regions of the CNS. Biosynthesis of angiotensinogen is stimulated by inflammation, insulin, estrogens, glucocorticoids, thyroid hormone, and AngII. During pregnancy, plasma levels of angiotensinogen increase several-fold owing to increased estrogen.

**Figure 26–1 Components of the RAS.** The heavy arrows show the classical pathway, and the light arrows indicate alternative pathways. Receptors involved: AT₁, AT₂, AT₄, Mas, MrgD, and PRR. AP, aminopeptidase; E, endopeptidases; PCP, prolylcarboxylpeptidase.

**Figure 26–2 Biological activation of prorenin and pharmacological inhibition of renin.** Prorenin is inactive; accessibility of AGT (angiotensinogen) to the catalytic site is blocked by the propeptide (black segment). The blocked catalytic site can be activated nonproteolytically by the binding of prorenin to the PRR or by proteolytic removal of the propeptide. The competitive renin inhibitor aliskiren has a higher affinity (~0.1 μM) for the active site of renin than does AGT (~1 μM).
Circulating levels of angiotensinogen are approximately equal to the $K_v$ of renin for its substrate (~1 μM). Consequently, the rate of AngII synthesis, and therefore blood pressure, can be influenced by changes in angiotensinogen levels. Oral contraceptives containing estrogen increase circulating levels of angiotensinogen and can induce hypertension. A missense mutation in the angiotensinogen gene (M235T in angiotensinogen) that increases plasma levels of angiotensinogen is associated with essential and pregnancy-induced hypertension (Sethi et al., 2003). Urinary angiotensinogen levels are considered an index for local intrarenal RAS activity and are elevated in patients with hypertension and progressive renal disease (Kobori and Urushihara, 2013).

**Angiotensin-Converting Enzyme**

Angiotensin-converting enzyme (ACE, kininase II, dipeptidyl carboxypeptidase) is an ectoenzyme and glycoprotein with an apparent molecular weight of 170 kDa. Human ACE contains 1277 amino acid residues and two homologous domains, each with a catalytic site and a Zn2+-binding region. ACE has a large amino-terminal extracellular domain, a short carboxyl-terminal intracellular domain, and a 22–amino acid transmembrane hydrophobic region that anchors the ectoenzyme. ACE is rather nonspecific and cleaves dipeptide units from substrates with diverse amino acid sequences. Preferred substrates have only one free carboxyl group in the carboxyl-terminal amino acid, and proline must not be the penultimate amino acid; thus, the enzyme does not degrade AngII. ACE is identical to kininase II, the enzyme that inactivates bradykinin and other potent vasodilator peptides. Although slow conversion of AngI to AngII occurs in plasma, the very rapid metabolism that occurs in vivo is due largely to the activity of membrane-bound ACE present on the luminal surface of endothelial cells throughout the vascular system (Guang et al., 2012).

The ACE gene contains an insertion/deletion polymorphism in intron 16 that explains the large phenotypic variance in serum ACE levels. The deletion allele, associated with higher levels of serum ACE and increased metabolism of bradykinin, may confer an increased risk of hypertension, cardiac hypertrophy, atherosclerosis, and diabetic nephropathy (Sayed-Tabatabaei et al., 2006; Hadjadj et al., 2001).

![Figure 26-3](image)

**Figure 26-3** *Physiological pathways, feedback loops, and pharmacological regulation of the RAS.* Schematic portrayal of the three major physiological pathways regulating renin release. See text for details.

![Figure 26-4](image)

**Figure 26-4** *Regulation of JG cell renin release by the macula densa.* Mechanisms by which the MD regulates renin release. Changes in tubular delivery of NaCl to the MD cause appropriate signals to be conveyed to the JG cells. Sodium depletion upregulates nNOS and COX-2 in the MD to enhance production of PGs. PGs and catecholamines stimulate adenylyl cyclase (AC) and cAMP production and thence renin release from the JG cells. Increased NaCl transport depletes ATP and increases adenosine (ADO) levels. Adenosine diffuses to the JG cells and inhibits cAMP production and renin release via Gi-coupled A1 receptors. Increased NaCl transport in the MD augments the efflux of ATP, which may inhibit renin release directly by binding to P2Y receptors and activating the G$_\alpha$-PLC-IP$_3$-Ca$^{2+}$ pathway in JG cells. Circulating AngII also inhibits renin release on JG cells via G$_\alpha$-coupled AT$_1$ receptors. Expression upregulated by chronic Na$^+$ depletion.
Angiotensin-Converting Enzyme 2

A carboxypeptidase, ACE2, cleaves one amino acid from the carboxyl terminal to convert AngII to Ang(1–7). ACE2 may also convert AngI to Ang(1–9), which is then converted to Ang(1–7) by ACE, nephrin, and endopeptidases (Santos, 2014). ACE2 contains a single catalytic domain that is 42% identical to the two catalytic domains of ACE. AngII is the preferred substrate for ACE2, with 400-fold higher affinity than AngI (Guang et al., 2012).

The counterregulation of the actions of AngII by ACE2 occur in at least two ways:

1. It decreases AngII levels and limits its effects by metabolizing it to Ang(1–7).
2. It increases levels of Ang(1–7), which acts on Mas receptors to oppose AngII actions (Figure 26–5).

Angiotensin-converting enzyme 2 is not inhibited by the standard ACE inhibitors and has no effect on bradykinin. Reduced expression or deletion of ACE2 is associated with hypertension, defects in cardiac contractility, and elevated levels of AngII. Inhibition of AT1 receptors by ARBs increases the expression of ACE2 gene decreases blood pressure and prevents AngII-induced cardiac hypertrophy in hypertensive rats. ACE2 is protective against diabetic nephropathy through the Ang(1–7)/Mas receptor pathway (Varagic et al., 2014). Ang(1–9), which is generated from AngII by ACE2, may also have vasodilating and protective effects by activating AT2 receptors (Etelvino et al., 2014). In addition, ACE2 metabolizes Apelin peptides, serves as a receptor for the severe acute respiratory syndrome coronavirus (SARS), and has been reported to interact with and regulate amino acid transporters (Kuba et al., 2013).

Alternative Pathways for Angiotensin II Biosynthesis

Angiotensin II may be generated through ACE-independent pathways or “ACE escape.” Angiotensinogen is converted to AngI, or directly to AngII by cathepsin G and tonin. Enzymes that convert AngI to AngII include cathepsin G, chymostatin-sensitive AngII-generating enzyme, and chymase. Chymase contributes to tissue conversion of AngII to AngI, particularly in the heart and kidneys. The major source of chymase is mast cells (Ferrario et al., 2014; Paul et al., 2006).

Angiotensinases

Angiotensinases include aminopeptidases, endopeptidases, carboxypeptidases, and other peptidases that metabolize angiotensin peptides; none is specific.

Angiotensin Peptides and Their Receptors

Table 26–1 shows the RAS peptides, their receptors, and overall effects of the receptor-peptide interactions.

AngII-AT1 Receptor Axis

Angiotensin II binds to specific GPCRs, designated AT1 and AT2. The hypertensive, renal, and hypertrophic effects of AngII are mediated by activation of the AT1 receptor (Dell’Italia, 2011). The AT1 receptor gene contains a polymorphism (A1166C) associated with hypertension, hypertrophic cardiomyopathy, and coronary artery vasostenosis. Moreover, the C allele synergizes with the ACE deletion allele with regard to increased risk of coronary artery disease (Álvarez et al., 1998). Preeclampsia is associated with the development of agonistic autoantibodies against the AT1 receptor in some cases (Xia et al., 2013).

AngII-AT1 Receptor-Effecter Coupling. The AT1 receptors link to a large array of signal transduction systems to produce effects that vary with cell type and that are a combination of primary and secondary responses. AT1 receptors couple to several heterotrimeric G proteins, including Gq, Gi1/2/3, and G12/13, and the GPCR characteristics of being substrates for phosphorylation and desensitization by G protein-coupled receptor kinases (GRKs), interacting with β-arrestin, and being subsequently internalized.

In most cell types, AT1 receptors couple to Gq to activate the PLCβ-Ca2+-IP3-Ca2+ pathway. Secondary to Gq activation, activation of PKC, PLA2, and PLD and eicosanoid production, Ca2+-dependent and MAP kinases, caspase-3, and p38 mitogen-activated protein kinases, and ERK1/2, and the GPCR characteristics of being substrates for phosphorylation and desensitization by G protein-coupled receptor kinases (GRKs), interacting with β-arrestin, and being subsequently internalized. Activation of Gq may occur and will reduce the activity of adenylyl cyclase, lowering cellular cyclic AMP content; however, there also is evidence for Gq → Gs cross talk such that activation of the AT1 receptor leads to activation of Gq, and activation of Gs lead to activation of tyrosine kinases and small G proteins such as Rap. Ultimately, the Jak/STAT pathway may be activated and a variety of transcriptional regulatory pathways involved.

factors induced. By these mechanisms, angiotensins influence the expression of a host of gene products relating to cell growth and the production of components of the extracellular matrix. Through AT₁ receptors, AngII also stimulates the activity of a membrane-bound NADH/NADPH oxidase that generates ROS. ROS may contribute to some of the biochemical effects (activation of MAP kinase, tyrosine kinase, and phosphatases; inactivation of NO; and expression of monocyte chemottractant protein-1) and physiological effects (acute effects on renal function, chronic effects on blood pressure, and vascular hypertrophy and inflammation) of AngII (Mehta and Griendling, 2007). The relative importance of these myriad signal transduction pathways in mediating biological responses to AngII is tissue specific. The AT₂ receptor is structurally flexible and may be activated, independently of AngII binding, by conformational changes such as mechanical stress (Kim et al., 2012). Functions of the AT₂ receptor may be modified by dimerization with AT₃ receptor, the bradykinin B₂ receptor, the β₂ adrenergic receptor, and the apelin receptor (Goupil et al., 2013).

**AngII-AT₁ Receptor Axis**

Activation of the AT₁ receptors counteracts many of the effects of the AT₂ receptors by having antiproliferative, anti-inflammatory, vasodilatory, natriuretic, and antihypertensive effects (Figure 26–5). The AT₂ receptors are distributed widely in fetal tissues, but their distribution is more restricted in adults. Expression of AT₂ receptors is upregulated in cardiovascular diseases, including heart failure, cardiac fibrosis, and ischemic heart disease (Jones et al., 2008). Signaling through the AT₂ receptor is mediated by G protein-dependent (Gₛ and Gₛ) and G protein–independent pathways. Consequences of AT₂ receptor activation include activation of MAP kinases and ERK 1/2; inhibition of Ca²⁺ channel functions; and enhancing NO, cyclic GMP, and bradykinin production. The AT₂ receptors can bind the AT₁ receptors to antagonize and reduce their expression; and the AT₂ receptors can form heterodimers with the bradykinin B₂ receptor to enhance NO production (Jones et al., 2008; Padia and Carey, 2013).

**Angiotensin (1–7)/Mas Receptor Axis**

The ACE2/Ang(1–7)/Mas receptor axis is a negative regulator of the pressor, profibrotic, and antinatriuretic effects of the ACE/AngII/AT₁ receptor axis of the RAS (Figure 26–5). Ang(1–7) is generated in several ways (Figure 26–1):

- from AngII by ACE2;
- from AngII by carboxypeptidases;
- from AngII by endopeptidases; and
- from Ang by a two-step conversion, by ACE2 to Ang(1–9) and then to Ang(1–7) by ACE or nephrilysin.

The antihypertensive effects of Ang(1–7) are mediated through binding to the Mas receptors, although Ang(1–7) can bind and activate AT₁ receptors (Gironacci et al., 2014). Activation of the Mas receptor by Ang(1–7) induces vasodilation, stimulates PLK/Akt pathway that promotes NO production, potentiates the vasodilatory effects of bradykinin, and inhibits AngII-induced activation of ERK1/2 and NfκB; it has antiangiogenic, antiproliferative, and antithrombotic effects; and it is renoprotective and cardio-protective in cardiac ischemia and heart failure (Fraga-Silva et al., 2013; Varagic et al., 2014). The Mas proto-oncogene encodes an orphan GPCR. Knockout of the Mas gene in mice causes increased vascular resistance and cardiac dysfunction (Santos, 2014; Varagic et al., 2014). The Mas receptor is present in the brain, and its activation is associated with improved memory and cognition (Gironacci et al., 2014). The capacity of Ang(1–7) to counterbalance the actions of AngII may depend on the ratio of ACE/AngII/AT₁ receptor activity to ACE2-Ang(1–7)-Mas receptor activity (see Figure 26–5; Santos, 2014; Romero et al., 2015). Pharmacologically enhancing the ACE2-Ang(1–7)-Mas receptor pathway using ACE2 activators and specific Mas receptor agonists could provide new avenues for modulating RAS in cardiovascular and renal disease.

**Angiotensin III**

Angiotensin III, also called Ang(2–8), can be formed by the action of aminopeptidase A on AngIIR or by the action of ACE on Ang(2–10). AngIII binds to both AT₁ and AT₂ receptors, causing effects qualitatively similar to those of AngII. AngII and AngIII stimulate aldosterone secretion with equal potency; however, AngIII is less efficacious in elevating blood pressure (25%) and stimulating the adrenal medulla (10%). Data from model systems make clear that AngIII and the shorter angiotensin-derived peptides have significant activity, especially at the AT₂ receptor, and that there may be instances where AngIII is the active endogenous ligand (Bosnyak et al., 2011).

**Angiotensin IV/AT₄ Receptor Axis**

Angiotensin IV, also called Ang(3–8), is formed from AngIII through the catalytic action of aminopeptidase N. Central and peripheral actions of AngIV are mediated through a specific AT₄ receptor that was identified as IRAP (insulin-regulated aminopeptidase) (see Figure 26–1). This receptor is a single transmembrane protein (1025 amino acids) that colocalizes with the glucose transporter type 4. AT₄ receptors are detectable in a number of tissues, such as heart, vasculature, adrenal cortex, and brain regions processing sensory and motor functions. AngIV-dependent AT₄ receptor activation regulates cerebral blood flow, is neuroprotective, and facilitates long-term potentiation, memory consolidation, and cognition (Wright et al., 2013). AngIV binding to the AT₄ receptor inhibits the catalytic activity of IRAP and enables accumulation of various neuropeptides linked to memory potentiation. Other actions include renal vasodilation, natriuresis, neuronal differentiation, hypertrophy, inflammation, and extracellular matrix remodeling. Analogues of AngIV are being developed for their therapeutic potential in Alzheimer disease and head injury (Albiston et al., 2007; Wright et al., 2013).

**New Physiologically Active Angiotensin Peptides**

New biologically active angiotensin peptides and their receptors have been identified (Table 26–1). These peptides include Ang(1–9), AngA and alamandine, Ang(3–7), and proangiotensin/Ang(1–12) (Ferrario et al., 2014). Ang(1–9) is generated from AngI by the action of ACE2, carboxypeptidase A, and cathepsin. Ang(1–9) has cardioprotective and antiproliferative effects reportedly mediated through binding to AT₁ receptors and the release of NO (Etelvino et al., 2014). Almandine is produced from Ang(1–7) by the decarboxylation of the Asp residue into Ala, residue on the N-terminal. Almandine acts through the Mg/Δ to mediate vasodilatory and antifibrotic effects similar to Ang(1–7). Almandine is an ACE substrate and may act as an ACE inhibitor. Almandine is elevated in patients with chronic renal disease (Etelvino et al., 2014).

Angiotensin A is an octapeptide produced by decarboxylation of the Asp residue of AngII into Ala, AngA binds to both AT₁ and AT₂ receptors and has effects similar to, but less potent than, AngII. AngA is reported to be elevated in patients with end-stage renal disease (Ferrario et al., 2014). Ang(3–7) is generated from AngIV and binds AT₂ receptors (Wright et al., 2013). Proangiotensin or Ang(1–12) is generated from angiotensinogen through a nonrenin pathway and can be converted to AngII through action of chymase. Ang(1–12) can bind to the AT₂ receptors and may be a precursor for autocrine/intracrine production of AngII (Ferrario et al., 2014).

**Local (Tissue) Renin-Angiotensin System**

Local (tissue) RAS is a tissue-based AngII-producing system that plays a role in hypertension, nephropathy, inflammation, remodeling, and apoptosis. ACE is present on the luminal face of vascular endothelial cells throughout the circulation; circulating (pro)renin can bind the PRR in the arterial wall and other tissues to mediate local generation of AngII (Campbell, 2014; Paul et al., 2016). Tissue RAS is also an autocrine and intracrine mechanism that can generate AngII and other bioactive angiotensin peptides independently of the renal/hepatic-based system. Many tissues—including the brain, pituitary, blood vessels, heart, kidney, and adrenal gland—produce renin, angiotensinogen, ACE and ACE2, chymase, PRR, and angiotensins I, II, III, IV, Ang(1–7) and the AT₁, AT₂, and Mas receptors (Campbell, 2014; Ferrario et al., 2014). Selective activation of the local RAS components is tissue specific and likely affects the pathophysiological outcomes in disease.
The (Pro) Renin Receptor

(Pro)renin/PRR binding enhances tissue-RAS activity and induces profibrotic intracellular signaling events that are independent of AngII production (Figure 26–6). The PRR is abundant in the heart, brain, eye, adrenals, placenta, adipose tissue, liver, and kidneys. The PRR gene is located in the locus p11.4 of the X chromosome and is named ATP6ap2 (ATPase-6 accessory protein 2). Knockout of the PRR gene is lethal, indicating an important role for PRR in development. In humans, mutations in the PRR gene are associated with mental retardation and epilepsy (Nguyen and Danser, 2008). Human PRR is a single transmembrane protein of 350 amino acids (~37 kDa). PRR is composed of N-terminal extracellular domain that binds (pro)renin, a transmembrane domain and a cytosolic domain that are associated with Vacuolar-H+-ATPase (V-ATPase) activity (Nguyen, 2011). Cleavage of the extracellular domain of PRR by furin or ADAM19 produces the N-terminal segment, soluble PRR, found in plasma and urine. Increased levels of urinary soluble PRR correlate with elevated urinary angiotensinogen levels, a biomarker of intrarenal RAS activity (Oshima et al., 2014).

(Pro)renin receptor binds (pro)renin with nanomolar affinity and high specificity to enhance the tissue-RAS. Binding of (pro)renin to PRR augments the catalytic activity of renin and induces nonproteolytic activation of prorenin by unfolding the 43 amino acid–prorenin prosegment and exposing the enzymatic cleft (Figure 26–2). Bound, activated (pro)renin catalyzes the conversion of angiotensinogen to AngI, with the consequent formation of AngII. The binding of (pro)renin to PRR also induces profibrotic signaling events that are AngII independent (Figure 26–6), including activation of ERK1/2, p38, tyrosine kinases, COX-2, TGF-β gene expression, and PAI-1 (Nguyen and Danser, 2008). These signaling pathways are not blocked by ACE inhibitors or AT1 receptor antagonists and are reported to contribute to fibrosis, nephrosis, and end-organ damage (Kaneshiro et al., 2007). Overexpression of the human PRR in transgenic animals increases plasma aldosterone levels in the absence of changes in plasma renin levels and induces hypertension and nephropathy. Rats overexpressing PRR exhibit expression of COX-2 in the macula densa and develop proteinuria and glomerulosclerosis that increase with aging (Kaneshiro et al., 2007).

Circulating plasma concentrations of (pro)renin are elevated 100-fold in diabetic patients and are associated with increased risk of nephropathy, renal fibrosis, and retinopathy (Nguyen and Danser, 2008). The blockade of PRR by administration of a peptide antagonist, known as “handle region peptide” (HRP), was reported to be protective in animal models against diabetic nephropathy and retinopathy (Oshima et al., 2014); however, the efficacy and specificity of HRP was not strongly confirmed by other groups (reviewed by Binger and Muller, 2013; Nguyen, 2011). The pathophysiological significance of (pro)renin/PRR interaction outside the local tissue RAS is still unclear (Lu et al., 2016).

The PRR participates in many functions that are independent of (pro)renin binding. PRR functions as an accessory protein essential for V-ATPase activity, which is required for intracellular acidity, receptor-mediated endocytosis, and activation of lysosomal and autophagosomal enzymes (Oshima et al., 2014). Cardiomyocyte-specific PRR knockout mice and podocyte-specific PRR knockout mice develop lethal organ-specific failure due loss of V-ATPase and the dysregulation of intracellular acidification and autophagic pathways (Binger and Muller, 2013). PRR also participates in the activation of Wnt/β-catenin and Wnt/plamin cell polarity signaling pathways that are important in cell polarization in the plane of tissue (Nguyen, 2011). PRR reportedly can regulate LDL uptake and metabolism. In hepatocytes, silencing PRR expression decreased cellular LDL uptake by decreasing expression of LDL receptor and sortelin 1 protein, a regulator of LDL uptake and metabolism and a PRR-interacting protein (Lu et al., 2016). (Pro)renin also binds to mannose-6-phosphate receptor, an insulin-like growth factor II receptor that functions as a clearance receptor (Nguyen and Danser, 2008).

Functions and Effects of Angiotensin II

Angiotensin II increases total peripheral resistance (TPR) and alters renal function and cardiovascular structure (Figure 26–7). Modest increases in plasma concentrations of AngII acutely raise blood pressure; on a molar basis, AngII is about 40 times more potent than NE; the EC50 of AngII for acutely raising arterial blood pressure is about 0.3 nM. When a single moderate dose of AngII is injected intravenously, systemic blood pressure begins to rise within seconds, peaks rapidly, and returns to normal within minutes (Figure 26–8). This rapid pressor response to AngII is due to a swift increase in TPR—a response that helps to maintain arterial blood pressure in the face of an acute hypotensive challenge (e.g., blood loss or vasodilation). Although AngII increases cardiac contractility directly (via opening voltage-gated Ca2+ channels in cardiac myocytes) and increases heart rate indirectly (via facilitation of sympathetic tone, enhancing adrenergic neurotransmission, and provoking adrenal catecholamine release), the rapid increase in arterial blood pressure activates a baroreceptor reflex that decreases sympathetic tone and increases vagal tone. Thus, depending on the physiological state, AngII may increase, decrease, or not change cardiac contractility, heart rate, and cardiac output. Changes in cardiac output therefore contribute little, if at all, to the rapid pressor response induced by AngII.

AngII also causes a slow pressor response that helps to stabilize arterial blood pressure over the long term. A continuous infusion of initially subpressor doses of AngII gradually increases arterial blood pressure, with
the maximum effect requiring days to achieve. This slow pressor response probably is mediated by a decrement in renal excretory function that shifts the renal pressure–natriuresis curve to the right (see the next section).

AngII stimulates the synthesis of endothelin 1 and superoxide anion, which may contribute to the slow pressor response.

Effects on the CNS
Angiotensin II, binding to AT receptors, augments NE release from sympathetic nerve terminals by inhibiting the reuptake of NE into nerve terminals and by enhancing the vascular response to NE in model systems (see Chapter 12).

Mechanisms by Which Angiotensin II Increases Total Peripher al Resistance
Angiotensin II increases peripheral resistance via direct and indirect effects on blood vessels (Figure 26–7).

Direct Vasconstriction
Angiotensin II constricts precapillary arterioles and, to a lesser extent, postcapillary venules by activating AT receptors located on vascular smooth muscle cells and stimulating the Gq-PLC-IP3-Ca2+ pathway. AngII has differential effects on vascular beds. Direct vasoconstriction is strongest in the kidneys (Figure 26–8) and somewhat less in the splanchnic bed. AngII-induced vasoconstriction is much less in vessels of the brain and still weaker in those of the lung and skeletal muscle. Nevertheless, high circulating concentrations of AngII may decrease cerebral and coronary blood flow.

Enhancement of Peripheral Noradrenergic Neurotransmission
Angiotensin II, binding to AT receptors, augments NE release from sympathetic nerve terminals by inhibiting the reuptake of NE into nerve terminals and by enhancing the vascular response to NE in model systems (see Chapter 12).

Effects on the CNS
Angiotensin II increases sympathetic tone. Small amounts of AngII infused into the vertebral arteries cause an increase in arterial blood pressure. This response reflects effects of the hormone on circumventricular nuclei that are not protected by a blood-brain barrier (e.g., area postrema, subfornical organ, organum vasculosum of the lamina terminalis).

Mechanisms by Which Angiotensin II Regulates Renal Function
Angiotensin II has pronounced effects on renal function, reducing the urinary excretion of Na+ and water while increasing the excretion of K+.

Release of Catecholamines From the Adrenal Medulla
Angiotensin II stimulates the release of catecholamines from the adrenal medulla by promoting Ca2+ entry secondary to depolarization of chromaffin cells.

Release of Aldosterone From the Adrenal Cortex
Angiotensin II stimulates the zona glomerulosa of the adrenal cortex to increase the synthesis and secretion of aldosterone and augments responses to other stimuli (e.g., ACTH, K+). Increased output of aldosterone is

Figure 26–9 Pressure-natriuresis curve: effects of Na+ intake on renin release (AngII formation) and arterial blood pressure. Inhibition of the RAS will cause a large drop in blood pressure in Na+-depleted individuals. (Modified with permission from Jackson EK, Branch RA, Margolius HS, Oates JA. Physiological functions of the renal prostaglandin, renin, and kallikrein systems. In: Seldin DW, Giebisch GH, eds. The Kidney: Physiology and Pathophysiology. Vol 1. Lippincott Williams & Wilkins, Philadelphia, 1985, 624.)

renal failure in patients with bilateral renal artery stenosis or in patients with unilateral stenosis who have only a single kidney.

Mechanisms by Which Angiotensin II Alters Cardiovascular Structure

Pathological alterations involving cardiovascular hypertrophy and remodeling increase morbidity and mortality. The cells involved include vascular smooth muscle cells, cardiac myocytes, and fibroblasts. AngII induces hypertrophy of cardiac myocytes; stimulates the migration, proliferation, and hypertrophy of vascular smooth muscle cells; increases extracellular matrix production by vascular smooth muscle cells; and increases extracellular matrix production by cardiac fibroblasts. In addition, AngII alters extracellular matrix formation and degradation indirectly by increasing aldosterone production and mineralocorticoid receptor activation. The adverse cardiovascular remodeling induced by AngII can be reduced but not entirely prevented by mineralocorticoid receptor antagonists.

Hemodynamically Mediated Effects of Angiotensin II on Cardiovascular Structure

In addition to the direct cellular effects of AngII on cardiovascular structure, changes in cardiac preload (volume expansion owing to Na+ retention) and afterload (increased arterial blood pressure) probably contribute to cardiac hypertrophy and remodeling. Arterial hypertension also contributes to hypertrophy and remodeling of blood vessels.

Role of the RAS in Long-Term Maintenance of Arterial Blood Pressure Despite Extreme Dietary Na+ Intake

Arterial blood pressure is a major determinant of Na+ excretion. This is illustrated graphically by plotting urinary Na+ excretion versus mean arterial blood pressure (Figure 26–9), a plot known as the renal pressure–natriuresis curve. Over the long term, Na+ excretion must equal Na+ intake; therefore, the set point for long-term levels of arterial blood pressure can be obtained as the intersection of a horizontal line representing Na+ intake with the renal pressure–natriuresis curve. The RAS plays a major role in maintaining a constant set point for long-term levels of arterial blood pressure despite extreme changes in dietary Na+ intake. When dietary Na+ intake is low, renin release is stimulated, and AngII acts on the kidneys to shift the renal pressure–natriuresis curve to the right. Conversely, when dietary Na+ is high, renin release is inhibited, and the withdrawal of AngII shifts the renal pressure–natriuresis curve to the left. When modulation of the RAS is blocked by drugs, changes in salt intake markedly affect long-term levels of arterial blood pressure.
Other Effects of the RAS

Expression of the RAS is required for the development of normal kidney morphology, particularly the maturational growth of the renal papilla. AngII causes a marked anorexigenic effect and weight loss, and high circulating levels of AngII may contribute to the anorexia, wasting, and cachexia of heart failure (Paul et al., 2006; Yoshida et al., 2013).

Inhibitors of the Renin-Angiotensin System

Drugs that interfere with the RAS play a prominent role in the treatment of cardiovascular disease. Besides β, blockers that inhibit renin release, the following three classes of inhibitors of the RAS are utilized therapeutically (Figure 26–10):

1. ACE inhibitors
2. Angiotensin receptor blockers
3. Direct renin inhibitors

All of these classes of agents will reduce the actions of AngII and lower blood pressure, but each has different effects on the individual components of the RAS (Table 26–2). Representative structures of agents inhibiting the RAS and reducing the effects of AngII are shown in Figure 26–11, near the end of the chapter.

</table>
Currently, 11 ACE inhibitors are available for clinical use in the U.S. They differ with regard to potency, whether ACE inhibition is primarily a direct effect of the drug itself or the effect of an active metabolite, and pharmacokinetics. All ACE inhibitors block the conversion of AngI to AngII and have similar therapeutic indications, adverse-effect profiles, and contraindications. Because hypertension usually requires lifelong treatment, quality-of-life issues are an important consideration in comparing antihypertensive drugs. With the exceptions of fosinopril, trandolapril, and quinapril (which display balanced elimination by the liver and kidneys), ACE inhibitors are cleared predominantly by the kidneys. Impaired renal function significantly diminishes the plasma clearance of most ACE inhibitors, and dosages of these drugs should be reduced in patients with renal impairment. Elevated PRA renders patients hyperresponsive to ACE inhibitor–induced hypotension, and initial dosages of all ACE inhibitors should be reduced in patients with high plasma levels of renin (e.g., patients with heart failure and during salt depletion including diuretic use). ACE inhibitors differ markedly in tissue distribution, and it is possible that this difference could be exploited to inhibit some local (tissue) RAS while leaving others relatively intact.

**Captopril.** Captopril is a potent ACE inhibitor with a $K_i$ of 1.7 nM. Given orally, captopril is absorbed rapidly and has a bioavailability of about 75%. Bioavailability is reduced by 25%–30% with food. Peak concentrations in plasma occur within an hour, and the drug is cleared rapidly, with a $t_{1/2}$ of about 2 h. Most of the drug is eliminated in urine, 40%–50% as captopril and the rest as captopril disulfide dimers and captopril–cysteine disulfide. The oral dose of captopril ranges from 6.25 to 150 mg 2–3 times daily, with 6.25 mg thrice daily or 25 mg twice daily appropriate for the initiation of therapy for heart failure or hypertension, respectively.

**Enalapril.** Enalapril maleate is a prodrug that is hydrolyzed by esterases in the liver to produce enalaprilat, the active dicarboxylic acid. Enalaprilat is a potent inhibitor of ACE with a $K_i$ of 0.2 nM. Enalapril is absorbed rapidly when given orally and has an oral bioavailability of about 60% (not reduced by food). Although peak concentrations of enalapril in plasma occur within an hour, enalaprilat concentrations peak only after 3–4 h. Enalapril has a $t_{1/2}$ of about 1.3 h, but enalaprilat, because of tight binding to ACE, has a plasma $t_{1/2}$ of about 11 h. Elimination is by the kidneys as either intact enalapril or enalaprilat. The oral dosage of enalapril ranges from 2.5 to 40 mg daily, with 2.5 and 5 mg daily appropriate for the initiation of therapy for heart failure and hypertension, respectively.

**Enalaprilat.** Enalaprilat is not absorbed orally but is available for intravenous administration when oral therapy is not appropriate.
Benazepril.

Cleavage of the ester moiety by hepatic esterases transforms benazepril into benazeprilat. Benazeprilat is absorbed rapidly but incompletely (37%) after oral administration (only slightly reduced by food). Benazepril is nearly completely metabolized to benazeprilat and to the glucuronide conjugates of benazepril and benazeprilat, which are excreted into the urine and bile; peak concentrations of benazepril and benazeprilat in plasma are achieved in 0.5–1 and 1–2 h, respectively. Benazeprilat has an effective plasma t1/2 of 10–11 h. With the exception of the lungs, benazeprilat does not accumulate in tissues. The oral dosage of benazepril ranges from 5 to 80 mg daily (single or divided dose).

Fosinopril.

Cleavage of the ester moiety by hepatic esterases transforms fosinopril into fosinoprilat. Fosinopril is absorbed slowly and incompletely (36%) after oral administration (rate but not extent reduced by food). Fosinopril is largely metabolized to fosinoprilat (75%) and to the glucuronide conjugates of fosinopril and fosinoprilat, which are excreted in the urine and bile; peak concentrations of fosinopril and fosinoprilat in plasma are achieved in about 12 h. Fosinopril does not accumulate in tissues. The oral dosage of lisinopril ranges from 5 to 40 mg daily (single or divided dose), with 5 and 10 mg daily appropriate for the initiation of therapy for heart failure and hypertension, respectively. A daily dose of 2.5 mg with close medical supervision is recommended for patients with heart failure who are hypotensive or have renal impairment.

Lisinopril.

Lisinopril is the lysine analogue of enalaprilat; unlike enalapril, lisinopril itself is active. In vitro, lisinopril is a slightly more potent ACE inhibitor than is enalaprilat. Lisinopril is absorbed slowly, variably, and incompletely (30%) after oral administration (not reduced by food); peak concentrations in plasma are achieved in about 7 h. It is excreted unchanged by the kidney with a plasma t1/2 of about 12 h. Lisinopril does not accumulate in tissues. The oral dosage of lisinopril ranges from 5 to 40 mg daily (single or divided dose), with 5 and 10 mg daily appropriate for the initiation of therapy for heart failure and hypertension, respectively. A daily dose of 2.5 mg with close medical supervision is recommended for patients with heart failure who are hypotensive or have renal impairment.

Ramipril.

Orally administered ramipril is absorbed rapidly (peak concentrations in 1 h); the rate but not extent of its oral absorption (50%–60%) is reduced by food. Ramipril is metabolized to ramiprilat by hepatic esterases and to inactive metabolites that are excreted predominantly by the kidneys. Peak concentrations of ramiprilat in plasma are achieved in about 3 h. Ramiprilat displays triphasic elimination kinetics (t1/2: values: 2–4, 9–18, and more than 50 h) This triphasic elimination is due to extensive distribution to all tissues (initial t1/2), clearance of free ramiprilat from plasma (intermediate t1/2), and dissociation of ramiprilat from tissue ACE (long terminal t1/2). The oral dosage of ramipril ranges from 1.25 to 20 mg daily (single or divided dose).

Moxepiril.

Moxepiril’s antihypertensive activity is due to its deesterified metabolite, moexiprilat. Moxepiril is absorbed incompletely, with bioavailability as moexiprilat of about 13%. Bioavailability is markedly decreased by food. The time to peak plasma concentration of moexiprilat is almost 1.5 h; the elimination t1/2 varies between 2 and 12 h. The recommended dosage range is 7.5–30 mg daily (single or divided doses). The dosage range is halved in patients who are taking diuretics or who have renal impairment.

Perindopril.

Perindopril erbumine is a prodrug, and 30%–50% of systemically available perindopril is transformed to perindoprilat by hepatic esterases. Although the oral bioavailability of perindopril (75%) is not affected by food, the bioavailability of perindoprilat is reduced by about 35%. Perindopril is metabolized to perindoprilat and to inactive metabolites that are excreted predominantly by the kidneys. Peak concentrations of perindoprilat in plasma are achieved in 3–7 h. Perindoprilat displays biphasic elimination kinetics with half-lives of 3–10 h (the major component of elimination) and 30–120 h (owing to slow dissociation of perindoprilat from tissue ACE). The oral dosage ranges from 2 to 16 mg daily (single or divided dose).

Therapeutic Uses of ACE Inhibitors

The ACE inhibitors are effective in the treatment of cardiovascular disease, heart failure, and diabetic nephropathy.

ACE Inhibitors in Hypertension.

Inhibition of ACE lowers systemic vascular resistance and mean, diastolic, and systolic blood pressures in various hypertensive states except when high blood pressure is due to primary aldosteronism (see Chapter 28). The initial change in blood pressure reflects an alteration of baroreceptor function with increased arterial compliance and the loss of the normal tonic influence of AngII on the zona glomerulosa of the adrenal cortex requires very small doses of potassium to cause aldosterone synthesis (see Chapter 28). However, increased responsiveness of tissues to normal levels of AngII makes some hypertensive patients sensitive to ACE inhibitors despite normal PRA.

The long-term fall in systemic blood pressure observed in hypertensive individuals treated with ACE inhibitors is accompanied by a leftward shift in the renal pressure–natriuresis curve (Figure 26–9) and a reduction in TPR, in which there is variable participation by different vascular beds. The kidney is a notable exception: Because the renal vessels are extremely sensitive to the vasoconstrictor actions of AngII, ACE inhibitors increase renal blood flow via vasodilation of the afferent and efferent arterioles. Increased renal blood flow occurs without an increase in GFR; thus, the filtration fraction is reduced.

The ACE inhibitors cause systemic arteriolar dilation and increase the compliance of large arteries, which contributes to a reduction of systolic pressure. Cardiac function in patients with uncomplicated hypertension generally is little changed, although stroke volume and cardiac output may increase slightly with sustained treatment. Baroreceptor function and cardiovascular reflexes are not compromised, and responses to postural changes and exercise are little impaired. Even when substantial lowering of blood pressure is achieved, heart rate and concentrations of catecholamines in plasma generally increase only slightly, if at all. This perhaps reflects an alteration of baroreceptor function with increased arterial compliance and the loss of the normal tonic influence of AngII on the sympathetic nervous system.

Aldosterone secretion is reduced, but not seriously impaired, by ACE inhibitors. Aldosterone secretion is maintained at adequate levels by other steroidogenic stimuli, such as ACTH and K+.

The activity of these secretagogues on the zona glomerulosa of the adrenal cortex requires very small trophic or permissive amounts of AngII, which always are present because ACE inhibition never is complete. Excessive retention of K+ is encountered.
in patients taking supplemental K+, in patients with renal impairment, or in patients taking other medications that reduce K+ excretion. The ACE inhibitors alone normalize blood pressure in about 50% of patients with mild-to-moderate hypertension. Ninety percent of patients with mild-to-moderate hypertension will be controlled by the combination of an ACE inhibitor and a Ca++ channel blocker, a β, adrenergic receptor blocker, or a diuretic. Diuretics augment the antihypertensive response to ACE inhibitors by rendering the patient's blood pressure renin dependent. Several ACE inhibitors are marketed in fixed-dose combinations with a thiazide diuretic or Ca++ channel blocker for the management of hypertension.

**ACE Inhibitors in Left Ventricular Systolic Dysfunction.** Unless contraindicated, ACE inhibitors should be given to all patients with impaired left ventricular systolic function whether or not they have symptoms of overt heart failure (see Chapter 29). Several large clinical studies demonstrated that inhibition of ACE in patients with systolic dysfunction prevents or delays the progression of heart failure, decreases the incidence of sudden death and myocardial infarction, decreases hospitalization, and improves quality of life. Inhibition of ACE commonly reduces afterload and systolic wall stress, and both cardiac output and cardiac index increase, so do indices of stroke work and stroke volume. In systolic dysfunction, AngII decreases arterial compliance, and this is reversed by ACE inhibition. Heart rate generally is reduced. Systemic blood pressure falls, sometimes steeply at the outset, but tends to return toward initial lev- els. Renovascular resistance falls sharply, and renal blood flow increases. Natriuresis occurs as a result of the improved renal hemodynamics, the reduced stimulus to the secretion of aldosterone by AngII, and the diminished direct effects of AngII on the kidney. The excess volume of body fluids contracts, which reduces venous return to the right side of the heart. A further reduction results from venodilation and an increased capacity of the venous bed.

Although AngII has little acute vasoconstrictor activity, long-term infusion of AngII increases venous tone, perhaps by central or peripheral interactions with the sympathetic nervous system. The response to ACE inhibitors also involves reductions of pulmonary arterial pressure, pulmonary capil- lary wedge pressure, and left atrial and left ventricular filling volumes and pressures. Consequently, preload and diastolic wall stress are diminished. The better hemodynamic performance results in increased exercise tolerance and suppression of the sympathetic nervous system. Cerebral and coronary blood flows usually are well maintained, even when systemic blood pressure is reduced. In heart failure, ACE inhibitors reduce ventricular dilation and tend to restore the heart to its normal elliptical shape. ACE inhibitors may reverse ventricular remodeling via changes in preload/afterload by pre- venting the growth effects of AngII on myocytes and by attenuating cardiac fibrosis induced by AngII and aldosterone.

**ACE Inhibitors in Acute Myocardial Infarction.** The beneficial effects of ACE inhibitors in acute myocardial infarction are particularly large in hypertensive and diabetic patients. Unless contraindicated (e.g., cardio- genic shock or severe hypotension), ACE inhibitors should be started immediately during the acute phase of myocardial infarction and can be administered along with thrombolytics, aspirin, and β adrenergic receptor antagonists (ACE Inhibitor Myocardial Infarction Collaborative Group, 1998). In high-risk patients (e.g., large infarct, systolic ventricular dys- function), ACE inhibition should be continued long term (see Chapters 27 and 28).

**ACE Inhibitors in Patients Who Are at High Risk of Cardiovascular Events.** Patients at high risk of cardiovascular events benefit considerably from treatment with ACE inhibitors (Heart Outcomes Prevention Study Investigators, 2000). ACE inhibition significantly decreases the rate of myocardial infarction, stroke, and death in patients who do not have left ventricular dysfunction but have evidence of vascular disease or diabetes and one other risk factor for cardiovascular disease. In patients with coronary artery disease but without heart failure, ACE inhibition reduces cardiovau- lar disease death and myocardial infarction (European Trial, 2003). The use of ACE inhibitors in type 1 diabetes is in part independent of blood pressure reduction. In addition, ACE inhibitors may decrease retinopathy progression in type 1 diabetics and attenuate the progression of renal insufficiency in patients with a variety of nondiabetic nephropathies (Ruggenenti et al., 2010). Several mechanisms participate in the renal protective effects of ACE inhibitors. Increased glomerular capillary pressure induces glomerular injury, and ACE inhibitors reduce this parameter by decreasing arterial blood pressure and by dilating renal efferent arterioles. ACE inhibitors increase the permeability selectivity of the filtering membrane, thereby diminishing exposure of the mesangium to proteinaceous factors that may stimulate mesangial cell proliferation and matrix production, two processes that contribute to expansion of the mesangium in diabetic nephropathy. Because AngII is a growth factor, reductions in the intrarenal levels of AngII may further attenuate mesangial cell growth and matrix production. ACE inhibitors increase Ang(1–7) levels by preventing its metabolism by ACE. Ang(1–7) binds to Mas receptors and has protective and antifibrotic effects (Santolí, 2014). In the setting of diabetes, at the level of renal epithelial podocytes, activation of AT, receptors leads to activation of protein kinase signaling cascades, cytoskeletal rearrangements, retraction of podocyte processes, and a reduction in proteins of the slit diaphragm, all resulting in increased permeability of the renal epithelium to proteins (proteinuria). ACE inhibitors reduce these effects of AngII (Márquez et al., 2015).

**ACE Inhibitors in Scleroderma Renal Crisis.** The use of ACE inhibitors considerably improves survival of patients with scleroderma renal crisis. **Adverse Effects of ACE Inhibitors**

In general, ACE inhibitors are well tolerated. The drugs do not alter plasma concentrations of uric acid or Ca++ and may improve insulin sensitivity and glucose tolerance in patients with insulin resistance and decrease cholesterol and lipoprotein (a) levels in proteinuric renal disease. **Hypotension.** A steep fall in blood pressure may occur following the first dose of an ACE inhibitor in patients with elevated PRA. Care should be exercised in patients who are salt depleted, are on multiple antihyper- tension drugs, or have congestive heart failure. **Cough.** In 5%–20% of patients, ACE inhibitors induce a bothersome, dry cough mediated by the accumulation in the lungs of bradykinin, substance P, or PAs. Thromboxane antagonism, aspirin, and iron supplementation reduce cough induced by ACE inhibitors. ACE dose reduction or switching to an ARB is sometimes effective. Once ACE inhibitors are stopped, the cough disappears, usually within 4 days. **Hyperkalemia.** Significant K+ retention is rarely encountered in patients with normal renal function. However, ACE inhibitors may cause hyperka- lemia in patients with renal insufficiency or diabetes or in patients taking K+- sparing diuretics, K+ supplements, β receptor blockers, or NSAIDs. **Acute Renal Failure.** Inhibition of ACE can induce acute renal insufficiency in patients with bilateral renal artery stenosis, stenosis of the artery to a single remaining kidney, heart failure, or volume depletion owing to diarrhea or diuretics. **Angioedema.** In 0.1%–0.5% of patients, ACE inhibitors induce rapid swelling in the nose, throat, mouth, glottis, larynx, lips, or tongue. Once ACE inhibitors are stopped, angioedema disappears within hours; meanwhile, the patient’s airway should be protected, and if necessary, epinephrine, an antihistamine, or a glucocorticoid should be adminis- tered. African Americans have a 4.5 times greater risk of ACE inhibitor–induced angioedema than Caucasians. Although rare, angioedema of the intestine (visceral angioedema) characterized by emesis, watery diarrhea, and abdominal pain also has been reported. ACE inhibitor– associated angioedema is a class effect, and patients who develop this adverse event should not be prescribed any other drugs within the ACE inhibitor class.
**Angiotensin II Receptor Blockers**

**HISTORY**

Attempts to develop therapeutically useful AngII receptor antagonists date to the early 1970s. Initial endeavors concentrated on angiotensin peptide analogues. Saralasin, 1-sarcosine, 8-isoleucine AngII, and other 8-substituted angiotensins are potent AngII receptor antagonists but were of no clinical value because of lack of oral bioavailability and unacceptable partial agonist activity. A breakthrough came in the early 1980s with the synthesis and testing of a series of imidazole–5–acetic acid derivatives that attenuated pressor responses to AngII in rats. Two compounds, S-8307 and S-8308, proved to be highly specific, albeit very weak, nonpeptide AngII receptor antagonists that were devoid of partial agonist activity (Dell'Italia, 2011). Through a series of stepwise modifications, the orally active, potent, and selective nonpeptide AT1 receptor antagonist losartan was developed and approved for clinical use in the U.S. in 1995. Since then, seven additional AT1 receptor antagonists (see Drug Facts for Your Personal Formulary table) have been approved. Although these AT1 receptor antagonists are devoid of partial agonist activity, structural modifications as minor as a methyl group can transform a potent antagonist into an agonist (Perelman et al., 1997).

**Pharmacological Effects**

The AngII receptor blockers bind to the AT1 receptor with high affinity and are more than 10,000-fold selective for the AT1 receptor over the AT2 receptor. Although binding of ARBs to the AT1 receptor is competitive, the inhibition by ARBs of biological responses to AngII often is functionally insurmountable. Insurmountable antagonism has the theoretical advantage of sustained receptor blockade even with increased levels of endogenous ligand and with missed doses of drug. ARBs inhibit most of the biological effects of AngII, which include AngII-induced (1) contraction of vascular smooth muscle; (2) rapid pressor responses; (3) slow pressor responses; (4) thirst; (5) vasopressin release; (6) aldosterone secretion; (7) release of adrenal catecholamines; (8) enhancement of noradrenergic neurotransmission; (9) increases in sympathetic tone; (10) changes in renal function; and (11) cellular hypertrophy and hyperplasia. ARBs reduce arterial blood pressure in animals with renovascular and genetic hypertension, as well as in transgenic animals overexpressing the renin gene. ARBs, however, have little effect on arterial blood pressure in animals with low-renin hypertension (e.g., rats with hypertension induced by NaCl and deoxycorticosterone) (Csajka et al., 1997).

**Do ARBs Have Therapeutic Efficacy Equivalent to That of ACE Inhibitors?**

Although both ARBs and ACE inhibitors of drugs block the RAS, they differ in several important aspects:

- **ARBs reduce activation of AT1 receptors more effectively than do ACE inhibitors.** ACE inhibitors reduce the biosynthesis of AngII by the action of ACE, but do not inhibit AngII generation via chymase and other ACE-independent AngII-producing pathways. ARBs block the actions of AngII via the AT1 receptor regardless of the biochemical pathway leading to AngII formation.
- **In contrast to ACE inhibitors, ARBs permit activation of AT2 receptors.** ACE inhibitors increase renin release, but block the conversion of AngI to AngII. ARBs also stimulate renin release; however, with ARBs, this translates into a several-fold increase in circulating levels of AngII. Because ARBs block AT1 receptors, this increased level of AngII is available to activate AT2 receptors.
- **ACE inhibitors and ARBs increase Ang(1–7) levels by different mechanisms.** ACE is involved in the clearance of Ang(1–7), so inhibition of ACE increases Ang(1–7) levels. With ARBs, AngII, the preferred substrate of ACE2, is converted to Ang(1–7).
- **ACE inhibitors increase the levels of a number of ACE substrates, including bradykinin and Ac-SDFK.**

Whether the pharmacological differences between ARBs and ACE inhibitors result in significant differences in therapeutic outcomes is an open question.

**Clinical Pharmacology**

**Oral bioavailability of ARBs generally is low (<50%) except for azilsartan (~60%) and irbesartan (~70%), and protein binding is high (>90%).**

**Candesartan Cilexetil.** Candesartan cilexetil is an inactive ester prodrug that is completely hydrolyzed to the active form, candesartan, during absorption from the GI tract (Figure 26–11). Peak plasma levels are obtained 3–4 h after oral administration; the plasma \( t_{1/2} \) is about 9 h. Plasma clearance of candesartan is due to renal elimination (33%) and biliary excretion (67%). The plasma clearance of candesartan is affected by renal insufficiency but not by mild–to–moderate hepatic insufficiency. Candesartan cilexetil should be administered orally once or twice daily for a total daily dose of 4–32 mg.

**Eprosartan.** Peak plasma levels are obtained 1–2 h after oral administration; the plasma \( t_{1/2} \) is 5–9 h. Eprosartan is metabolized in part to the glucuronide conjugate. Clearance is by renal elimination and biliary excretion. The plasma clearance of eprosartan is affected by both renal insufficiency and hepatic insufficiency. The recommended dosage of eprosartan is 400–800 mg/d in one or two doses.

**Irbesartan.** Peak plasma levels are obtained about 1.5–2 h after oral administration; the plasma \( t_{1/2} \) is 11–15 h. Irbesartan is metabolized in part to the glucuronide conjugate, and the parent compound and its glucuronide conjugate are cleared by renal elimination (20%) and biliary excretion (80%). The plasma clearance of irbesartan is unaffected by either renal or mild–to–moderate hepatic insufficiency. The oral dosage of irbesartan is 150–300 mg once daily.

**Losartan.** Approximately 14% of an oral dose of losartan is converted by CYP2C9 and CYP3A4 to the 5-carboxylic acid metabolite, EXP 3174, which is more potent than losartan as an AT1 receptor antagonist. Peak plasma levels of losartan and EXP 3174 occur about 1–3 h after oral administration, and the plasma half-lives are 2.5 and 6–9 h, respectively. The plasma clearance of losartan and EXP 3174 are via the kidney and liver (metabolism and biliary excretion) and are affected by hepatic but not renal insufficiency. Losartan should be administered orally once or twice daily for a total daily dose of 25–100 mg. Losartan is a competitive antagonist of the thromboxane \( A_2 \) receptor and attenuates platelet aggregation. EXP 3179, another metabolite of losartan without angiotensin receptor reduces, reduces COX-2 messenger RNA upregulation and COX-dependent PG generation (Krämer et al., 2002) (Figure 26–11).
olmesartan Medoxomil. Olmesartan medoxomil is an inactive ester prodrug that is completely hydrolyzed to the active form, olmesartan, during absorption from the GI tract. Peak plasma levels are obtained 1.4–2.8 h after oral administration; the plasma \( t_{1/2} \) is 10–15 h. Plasma clearance of olmesartan is due to both renal elimination and biliary excretion. Although renal impairment and hepatic disease decrease the plasma clearance of olmesartan, no dose adjustment is required in patients with mild-to-moderate renal or hepatic impairment. The oral dosage of olmesartan medoxomil is 20–40 mg once daily.

Telmisartan. Peak plasma levels are obtained 0.5–1 h after oral administration; the plasma \( t_{1/2} \) is about 24 h. Telmisartan is cleared from the circulation mainly by biliary secretion of intact drug. The plasma clearance of telmisartan is affected by hepatic but not renal insufficiency. The recommended oral dosage of telmisartan is 40–80 mg once daily.

Valsartan. Peak plasma levels occur 2–4 h after oral administration; food markedly decreases absorption; the plasma \( t_{1/2} \) is about 9 h. Valsartan is cleared from the circulation by the liver (~70% of total clearance), and hepatic insufficiency will reduce clearance. The oral dosage of valsartan is 80–320 mg once daily.

Azilsartan Medoxomil. The prodrug is hydrolyzed in the GI tract into the active form, azilsartan. The drug is available in 40- and 80-mg once-daily doses. At the recommended dose of 80 mg once a day, azilsartan medoxomil is superior to the maximal doses of valsartan and olmesartan in lowering blood pressure. Bioavailability of azilsartan is about 60% and is not affected by food. Peak plasma concentrations \( C_{\text{max}} \) are achieved within 1.5–3 h. The elimination \( t_{1/2} \) is about 11 h. Azilsartan is metabolized mostly by CYP2C9 into inactive metabolites. Elimination of the drug is 55% in feces and 42% in urine. About 15% of the dose is eliminated as unchanged azilsartan in urine. Plasma clearance is not affected by renal or hepatic insufficiency.

Angiotensin Receptor–Neprilysin Inhibitor. A combination of sacubitril and valsartan, marketed as Entresto, is a first-in-class drug that combines the AT\(_1\) receptor antagonistic moiety of valsartan with the neprilysin inhibitor moiety of sacubitril. The complex (sacubitril, valsartan, Na\(^+\), and water [1:1:3:2.5]) dissociates into sacubitril and valsartan after oral administration. Sacubitril bioavailability is about 60%, and it is highly protein bound (94%–97%). Sacubitril is further metabolized by esterases into the active metabolite LBQ657, which has a \( t_{1/2} \) of 11 h. The neprilysin inhibitor blocks the breakdown of natriuretic peptides ANP, BNP, and CNP, as well as Ang I and bradykinin. The drug combination lowers vascular resistance and increases blood flow. In clinical trial, this combination agent was reported to be superior to enalapril in decreasing the risk of deaths from cardiovascular causes and heart failure by 20% (McMurray et al., 2014).

Entresto is approved for treatment of heart failure with reduced ejection fraction, with a recommended dose of 100–400 mg daily, divided into two doses. Because the ACE/neprilysin inhibitor omapatrilat demonstrated an increased risk of angioedema, use of Entresto is contraindicated in conjunction with an ACE inhibitor or in patients with a history of angioedema during ACE inhibitor or ARB use. The drug should not be used in conjunction with an ARB or ACE inhibitor, and in patients with diabetes should not be used in conjunction with aliskiren. Potential adverse effects discussed for valsartan also apply to this sacubitril-valsartan combination.

A New Class of ARBs in Development. A \( \beta \)-arrestin-biased AT\(_1\) receptor blocker, TRV027 is a ligand that binds AT\(_1\) receptor and blocks \( G \) protein-coupled signaling while engaging \( \beta \)-arrestin. \( \beta \)-Arrestin functions as an adaptor protein that participates in receptor desensitization and internalization. In animal models, \( \beta \)-arrestin-biased AT\(_1\) receptor ligand increases myocyte contractility and protects against apoptosis (Kim et al., 2012). In phase II clinical studies, TRV027 decreased mean arterial pressure and was well tolerated. The safety and efficacy of TRV027 is being tested in the BLAST-HF study in patients with acute heart failure (Felker et al., 2015).

Therapeutic Uses of ARBs

All ARBs are approved for the treatment of hypertension. ARBs are renoprotective in type 2 diabetes mellitus, and many experts now consider them the drugs of choice for renoprotection in diabetic patients.

Irbesartan and losartan are approved for diabetic nephropathy. Losartan is approved for stroke prophylaxis, and valsartan and candesartan are approved for heart failure and to reduce cardiovascular mortality in clinically stable patients with left ventricular failure or left ventricular dysfunction following myocardial infarction. The efficacy of ARBs in lowering blood pressure is comparable with that of ACE inhibitors and other established antihypertensive drugs, with a favorable adverse-effect profile. ARBs also are available as fixed-dose combinations with HCTZ or amloclide (see Chapters 27–28) to ACE inhibitors.

The Losartan Intervention for Endpoint (LIFE) Reduction in Hypertension Study demonstrated the superiority of an ARB compared with a \( \beta \)-adrenergic receptor antagonist with regard to reducing stroke in hypertensive patients with left ventricular hypertrophy (Dahlöf et al., 2002). Also, irbesartan appears to maintain sinus rhythm in patients with persistent, long-standing atrial fibrillation (Madrid et al., 2002). Losartan is reported to be safe and highly effective in the treatment of portal hypertension in patients with cirrhosis and portal hypertension without compromising renal function (Schneider et al., 1999).

The ELITE (Evaluation of Losartan in the Elderly) study and a follow-up study (ELITE II) concluded that in elderly patients with heart failure, losartan is as effective as captopril in improving symptoms (Pitt et al., 2000). The VAHINT (Valsartan in Acute Myocardial Infarction) trial demonstrated that valsartan is as effective as captopril in patients with myocardial infarction complicated by left ventricular systolic dysfunction with regard to all-cause mortality (Pfeffer et al., 2003). Both valsartan and candesartan reduce mortality and morbidity in patients with heart failure (reviewed by Makani et al., 2013). Current recommendations are to use ACE inhibitors as first-line agents for the treatment of heart failure and to reserve ARBs for treatment of heart failure in patients who cannot tolerate or have an unsatisfactory response to ACE inhibitors.

The ARBs are renoprotective in type 2 diabetes mellitus, and many experts now consider them the drugs of choice for renoprotection in diabetic patients.

Dual Inhibition of the RAS. At present, there is contradictory evidence regarding the advisability of combining an ARB and an ACE inhibitor in patients with heart failure, with one study indicating that a combination of ARB and ACE inhibitors decreases morbidity and mortality in patients with heart failure, and another showing that combination therapy is associated with increased adverse effects and no added benefits (Dell’Italia, 2011; Makani et al., 2013; ONTARGET Investigators, 2008).

Adverse Effects

The ARBs are generally well tolerated. The incidence of angioedema and cough with ARBs is less than that with ACE inhibitors. As with ACE inhibitors, ARBs have teratogenic potential and should be discontinued in pregnancy. In patients whose arterial blood pressure or renal function is highly dependent on the RAS (e.g., renal artery stenosis), ARBs can cause hypotension, oliguria, progressive azotemia, or acute renal failure. ARBs may cause hyperkalemia in patients with renal disease or in patients taking K\(^+\) supplements or K\(^+\)-sparing diuretics. ARBs enhance the blood pressure–lowering effect of other antihypertensive drugs, a desirable effect but one that may necessitate dosage adjustment. There are rare postmarketing reports of anaphylaxis, abnormal hepatic function, hepatitis, neutropenia, leukopenia, agranulocytosis, pruritus, urticaria, hyponatremia, alopecia, and vasculitis, including Henoch-Schönlein purpura.

Direct Renin Inhibitors

Angiotensinogen is the only specific substrate for renin. DRIs inhibit the cleavage of AngI from angiotensinogen by renin, an enzymatic reaction that is the rate-limiting step for the subsequent generation of AngII. Aliskiren is the only DRI approved for clinical use.
Earlier renin inhibitors were orally inactive peptide analogues of the prorenin propeptide or analogues of renin-substrate cleavage site. Orally active, first-generation renin inhibitors (enalkiren, zankiren, CGP38560A, and remikiren) were effective in reducing AngII levels, but none of them made it past clinical trials due to their low potency, poor bioavailability, and short t1/2. Low-molecular-weight renin inhibitors were designed based on molecular modeling and crystallographic structural information of renin-substrate interaction (Wood et al., 2003). This led to the development of aliskiren, a second-generation renin inhibitor that is FDA approved for the treatment of hypertension. Aliskiren has blood pressure–lowering effects similar to those of ACE inhibitors and ARBs.

**Pharmacological Effects**

Aliskiren is a low-molecular-weight nonpeptide and a potent competitive inhibitor of renin. It binds the active site of renin to block conversion of angiotensinogen to AngI, thus reducing the consequent production of AngII. Aliskiren has a 10,000-fold higher affinity to renin (IC50 ~ 0.6 nM) than to any other aspartic peptidases. In healthy volunteers, aliskiren (40–640 mg/d) induces a dose-dependent decrease in blood pressure, reduces PRA and AngI and AngII levels, but increases PRC by 16- to 40-fold due to the loss of the short-loop negative feedback by AngII (Figure 26–2; Table 26–2). Aliskiren also decreases plasma and urinary aldosterone levels and enhances natriuresis (Nussberger et al., 2002).

**Clinical Pharmacology**

Aliskiren is recommended as a single oral dose of 150 or 300 mg/d. Bioavailability of aliskiren is low (~2.5%), but its high affinity and potency make it an effective agent in reducing AngII levels, even in the presence of high dietary sodium intake. Aliskiren has blood pressure–lowering effects similar to those of ACE inhibitors and ARBs.

pressure will alter the feedback loops that regulate the RAS and cause changes in the levels and activities of the system's components. These changes, summarized in Table 26–2, should be taken into account when interpreting laboratory evaluation of patients. Furthermore, during aliskiren treatment, the assay for PRA will be inhibited by persistence of aliskiren in this ex vivo reaction, whereas the renin concentration radioimmunoassay will not be inhibited.

Pathophysiology of Ischemic Heart Disease

The pathophysiological understanding of ischemic heart disease has seen major changes over the past two decades—from a concept of localized calcification causing progressive constrictions of coronary arteries, ischemia, and exercise-induced angina pectoris to a systemic inflammatory disease of the arteries, including the coronaries (therefore the CAD name). A key finding in this change of paradigm was that most infarct-causing occlusions occur at small-to-medium plaques (“active plaques”) by thrombosis rather than at hemodynamically relevant stenoses by progressive narrowing. Thus, in addition to the mere size of an obstructing plaque, the inflammatory activity of the atherosclerotic process, the stability of the plaque, and platelet reactivity appear to determine the prognosis (Libby et al., 2002).

Atherosclerosis encompasses increased lipid deposition in the subendothelial space (early plaque), endothelial dysfunction with decreased production of NO, less vasodilation and increased risk of platelet adhesion, influx of lipid scavenger cells (mainly macrophages), necrosis, sterile inflammation, proliferation of smooth muscle cells, and calcification and narrowing of the blood vessel by increasing plaque formation. If the endothelium covering of the plaque or the cell layer enclosing the necrotic core of the plaque disrupt, thrombogenic materials such as collagen are presented to the bloodstream, causing platelet adhesion, fibrin deposition, thrombus formation, and closure of the blood vessel.

Triggering factors can be not only acute inflammation (e.g., influenza), but also blood pressure peaks during physical exercise or emotional stress (e.g., demonstrated during a life-threatening emergency and in avid fans during football games). Importantly, the process is dynamic, and the net thrombus formation is the result of the balance between thrombosis and thrombolysis by the fibrinolytic system (plasminogen). The degree and the duration of coronary obstruction and thereby of the ischemia of downstream myocardium (and its size) determine the degree of necrosis of muscle tissue, that is, infarct size.

Taken together, important factors that determine the progress of CAD are the concentration of lipids in the blood, endothelial function, blood pressure (as a mechanical factor predisposing to plaque rupture), the activity of the inflammatory system, and the reactivity of pro- and antithrombotic systems. Patients with CAD should be advised not only to exercise regularly, stop smoking, and have blood pressure and body weight well controlled, but also to be treated with statins, aspirin, and β adrenergic receptor antagonists (β blockers) and have annual vaccinations against influenza. The widespread implementation of this combination drug regimen and the considerably improved treatment of ACSs likely account for the continuous reduction in MIs and age-corrected cardiovascular lethality in Western countries (−42% between 2000 and 2011; Mozaffarian et al., 2015). Interestingly, the incidence of the classical large STEMI is declining as that of smaller non-STEMI increases. This raises the hypothesis that the dominant pathogenesis of acute coronary thrombosis may have changed from the rupture of lipid-rich, inflammatory plaques (in the prestatin era) to the erosion of stable plaques (Libby and Pasterkamp, 2015).

Antiplatelet agents, fibrinolytic drugs, anticoagulants, and statins (HMG-CoA reductase inhibitors) are systematically discussed in Chapters 32 and 33. This chapter concentrates on pharmacotherapy for angina pectoris and myocardial ischemia.

Pathophysiology of Angina Pectoris

Angina pectoris, the primary symptom of ischemic heart disease, is caused by transient episodes of myocardial ischemia that are due to an imbalance in the myocardial oxygen supply-demand relationship. This imbalance may be caused by an increase in myocardial oxygen demand (which is determined by heart rate, ventricular contractility, and ventricular wall tension) or by a decrease in myocardial oxygen supply (primarily determined by coronary blood flow, but occasionally modified by the oxygen-carrying capacity of the blood), or sometimes by both (Figure 27–1). Because blood flow is inversely proportional to the fourth power of the artery’s luminal radius, the progressive decrease in vessel radius that characterizes coronary atherosclerosis can impair coronary blood flow and lead to symptoms of angina when myocardial O_2 demand increases, as with exertion (the so-called typical and most prevalent form of angina pectoris). In some patients, anginal symptoms may occur without any increase in myocardial O_2 demand, but rather as a consequence of an abrupt reduction in blood flow, as might result from coronary thrombosis (unstable angina or ACS) or localized vasospasm (variant or Prinzmetal angina). Regardless of the precipitating factors, the sensation of angina is similar in most patients. Typical angina is experienced as a heavy, pressing substernal discomfort (rarely described as a “pain”), often radiating to the left shoulder, flexor aspect of the left arm, jaw, or epigastrium. However, a significant minority of patients note discomfort in a different location or of a different character. Women, the elderly, and diabetics are more

Tx A2: thromboxane A2

The principal pharmacological agents used in the treatment of angina are nitrosodilators, β blockers (see Chapter 12), and Ca2+ channel blockers. In patients with typical exercise-induced angina on the basis of CAD, these antianginal agents improve the balance of myocardial O2 supply and O2 demand principally by reducing myocardial O2 demand by decreasing heart rate, myocardial contractility, or ventricular wall stress. Increased O2 supply by dilating the coronary vasculature may play an additional role and is the major effect of nitrosodilators and Ca2+ channel blockers in variant angina.

By contrast, the principal therapeutic goal in ACSs with unstable angina is to prevent or reduce coronary thrombus formation and increase myocardial blood flow; strategies include the use of antiplatelet agents and heparin, often accompanied by efforts to restore flow by mechanical means, including percutaneous coronary interventions using coronary stents, or (less commonly) emergency coronary bypass surgery. The principal therapeutic aim in variant or Prinzmetal angina is to prevent coronary vasospasm.

Antianginal agents may provide prophylactic or symptomatic treatment, but β blockers also reduce mortality, apparently by decreasing the incidence of sudden cardiac death associated with myocardial ischemia and infarction. The chronic use of organic nitrate vasodilators, which are highly efficacious in treatment of angina, is not associated with pattern over many years or may become unstable, increasing in frequency or severity and even occurring at rest. In typical stable angina, the pathological substrate is usually fixed atherosclerotic narrowing of an epicardial coronary artery, on which exertion or emotional stress superimposes an increase in myocardial O2 demand. In variant angina, focal or diffuse coronary vasospasm episodically reduces coronary flow. Patients also may display a mixed pattern of angina with the addition of altered vessel tone on a background of atherosclerotic narrowing. In most patients with unstable angina, rupture of an atherosclerotic plaque, with consequent platelet adhesion and aggregation, decreases coronary blood flow. Superimposed thrombosis may lead to the complete abrogation of blood flow. Atherosclerotic plaques with thinner fibrous caps appear to be more "vulnerable" to rupture.

Myocardial ischemia also may be silent, with electrocardiographic, echocardiographic, or radionuclide evidence of ischemia appearing in the absence of symptoms. While some patients have only silent ischemia, most patients who have silent ischemia have symptomatic episodes as well. The precipitants of silent ischemia appear to be the same as those of symptomatic ischemia. We now know that the ischemic burden (i.e., the total time a patient is ischemic each day) is greater in many patients than was recognized previously. In most trials, the agents that are efficacious in typical angina also are efficacious in reducing silent ischemia. β Blockers appear to be more effective than the Ca2+ channel blockers in the prevention of episodes. Therapy directed at abolishing all silent ischemia has not been shown to be of additional benefit over conventional therapy.

**Pharmacotherapy of Ischemic Heart Disease**

The principal pharmacological agents used in the treatment of angina are nitrosodilators, β blockers (see Chapter 12), and Ca2+ channel blockers. In patients with typical exercise-induced angina on the basis of CAD, these antianginal agents improve the balance of myocardial O2 supply and O2 demand principally by reducing myocardial O2 demand by decreasing heart rate, myocardial contractility, or ventricular wall stress. Increased O2 supply by dilating the coronary vasculature may play an additional role and is the major effect of nitrosodilators and Ca2+ channel blockers in variant angina.

By contrast, the principal therapeutic goal in ACSs with unstable angina is to prevent or reduce coronary thrombus formation and increase myocardial blood flow; strategies include the use of antiplatelet agents and heparin, often accompanied by efforts to restore flow by mechanical means, including percutaneous coronary interventions using coronary stents, or (less commonly) emergency coronary bypass surgery. The principal therapeutic aim in variant or Prinzmetal angina is to prevent coronary vasospasm.

Antianginal agents may provide prophylactic or symptomatic treatment, but β blockers also reduce mortality, apparently by decreasing the incidence of sudden cardiac death associated with myocardial ischemia and infarction. The chronic use of organic nitrate vasodilators, which are highly efficacious in treatment of angina, is not associated with

**Figure 27-1  Pharmacological modification of the major determinants of myocardial O2 supply.** When myocardial O2 requirements exceed O2 supply, an ischemic episode results. This figure shows the primary hemodynamic sites of action of pharmacological agents that can reduce O2 demand (left side) or enhance O2 supply (right side). Some classes of agents have multiple effects. Stents, angioplasty, and coronary bypass surgery are mechanical interventions that increase O2 supply. Both pharmacotherapy and mechanochemotherapy attempt to restore a dynamic balance between O2 demand and O2 supply.
improvements in cardiac mortality, and some investigators have suggested that chronic use of nitroglycerin may have adverse cardiovascular effects (Parker, 2004).

Besides symptomatic relief from angina pain conferred by antianginal drugs, patients with CAD should be treated with drugs that can reduce the progression of atherosclerosis and reduce the risk of coronary thrombosis and MI. Aspirin is used routinely in patients with myocardial ischemia, and daily aspirin at low doses reduces the incidence of clinical events (Fihn et al., 2012). The optimal dose appears to be between 75 and 150 mg/d (Montalescot et al., 2013), although most large studies have been done with a 325-mg dose. The oral ADP receptor antagonist clopidogrel was slightly superior to aspirin in patients with chronic atherosclerotic vascular disease and had a favorable safety profile (CAPRIE Steering Committee, 1996). When used in combination with aspirin in patients with ACS, clopidogrel reduced the cardiovascular death rate by 20%, but increased the incidence of major bleeding events by 38% (Yusuf et al., 2001). In patients with stable cardiovascular disease, clopidogrel conferred no benefit over aspirin and was associated with signs of harm in patients with multiple risk factors (Bhatt et al., 2006). Guidelines therefore recommend clopidogrel only as an alternative in patients with aspirin intolerance and advise against the routine use of dual platelet inhibition in patients with stable disease (Fihn et al., 2012; Montalescot et al., 2013). In contrast, dual platelet inhibition is routinely given in patients who underwent coronary artery stenting. The recommended time (1–12 months) varies depending on the intervention (e.g., bare metal vs. drug-eluting stent) and the risk profile of patients. The newer ADP receptor antagonists prasugrel and ticagrelor have a more useful pharmacokinetic profile and seem to have a better benefit/risk ratio than clopidogrel in the postintervention treatment phase (Cannon et al., 2010; Viviotti et al., 2007) but are not generally recommended as alternatives to clopidogrel in patients with stable CAD. Statins reduce mortality in patients with CAD. Although high-risk patients (including those with high plasma LDL cholesterol levels) have the greatest absolute benefit, the relative risk reduction of approximately 25% appears largely independent of baseline cholesterol blood levels. Statins should therefore be given to all patients with CAD. It is unclear whether ACEIs or angiotensin receptor blockers (see Chapter 26) reduce mortality or other end points in patients with CAD when given routinely in addition to aspirin, statins, and β blockers, but they are recommended for subgroups of patients with CAD with reduced left ventricular systolic function, hypertension, diabetes, or chronic kidney disease (Montalescot et al., 2013).

Coronary artery bypass surgery and percutaneous coronary interventions such as angioplasty and coronary artery stent deployment commonly complement pharmacological treatment. In some subsets of patients, percutaneous or surgical revascularization may have a survival advantage over medical treatment alone (Kappetein et al., 2012). Intra-coronary drug delivery using drug-eluting coronary stents represents an intersection of mechanical and pharmacological approaches in the treatment of CAD.

**Organic Nitrates**

The organic nitrate agents are prodrugs that are sources of NO. NO activates the soluble isofrom of guanylyl cyclase, thereby increasing intracellular levels of cGMP. In turn, cGMP promotes the dephosphorylation of the myosin light chain and the reduction of cytosolic Ca²⁺ and leads to the relaxation of smooth muscle cells in a broad range of tissues (see Figures 3-13, 3-17, and 44-7). The NO-dependent relaxation of vascular smooth muscle leads to vasodilation; NO-mediated guanylyl cyclase activation also inhibits platelet aggregation and relaxes smooth muscle in the bronchi and GI tract.

The broad biological response to nitrovasodilators reflects the existence of endogenous NO-modulated regulatory pathways. The endogenous synthesis of NO in humans is catalyzed by a family of NO synthases that oxidize the amino acid l-arginine to form NO, plus l-citrulline as a coproduct. There are three distinct mammalian NO synthases: nNOS, eNOS, and iNOS (see Chapter 3), and they are involved in processes as diverse as neurotransmission, vasomotion, and immunomodulation. In several vascular disease states, pathways of endogenous NO-dependent regulation appear to be deranged (reviewed in [Dudzinski et al., 2006]).
guanyl cyclase is elicted in substantial part by S-nitrosothiol. The different ALDH2 dependence of GTN and ISDN is clinically relevant because individuals of Asian origin carry an inactive ALDH2 variant and do not respond adequately to GTN but do respond to ISDN (Stamler, 2008).

The NO-stimulated elevation of cGMP activates PKG and modulates the activities of cyclic nucleotide PDEs (PDEs 2, 3, and 5) in a variety of cell types. In smooth muscle, the net result is reduced phosphorylation of myosin light chain, reduced Ca++ concentration in the cytosol, and relaxation (Figure 44–7). Reduced phosphorylation of myosin light chain is the result of decreased myosin light-chain kinase activity and increased myosin light-chain phosphatase activity and promotes vasorelaxation and smooth muscle relaxation in many tissues. cGMP is a substrate for PDE 5, whose inhibition by sildenafil and related compounds potentiates the action of nitrovasodilators (see Toxicity and Untoward Responses).

Hemodynamic Effects. The nitrovasodilators promote relaxation of vascular smooth muscle. For reasons not understood, GTN dilates large blood vessels (>200-μm diameter) more potently than small vessels, and preferential venodilation decreases venous return, leading to a fall in left ventricular filling pressure. That result in decreased myocardial O2 demand (see discussion of wall stress, and thereby reduced cardiac O2 demand (see discussion that follows). Systemic vascular resistance and arterial pressure are not or only mildly decreased, leaving coronary perfusion pressure unaffected. Heart rate remains unchanged or may increase slightly in response to a decrease in blood pressure. Pulmonary vascular resistance and cardiac output are slightly reduced. Doses of GTN that do not alter systemic arterial pressure may still produce arteriolar dilation in the face and neck, resulting in a facial flush, or dilation of meningeal arterial vessels, causing headache.

Higher doses of organic nitrates cause further venous pooling and may decrease arteriolar resistance as well, thereby decreasing systolic and diastolic blood pressure and causing pallor, weakness, dizziness, and activation of compensatory sympathetic reflexes. This can happen to such an extent that coronary flow is compromised, and the sympathetic increase in myocardial O2 demand overrides the beneficial action of the nitrovasodilators, leading to ischemia. In addition, sublingual nitroglycerin administration may produce bradycardia and hypotension, probably owing to activation of the Bezold-Jarisch reflex.

In patients with autonomic dysfunction and an inability to increase sympathetic outflow (multiple-system atrophy and pure autonomic failure are the most common forms, much less commonly seen in the autonomic dysfunction associated with diabetes), the fall in blood pressure consequent to the venodilation produced by nitrates cannot be compensated. In these clinical contexts, nitrates may reduce arterial pressure and coronary perfusion pressure significantly, producing potentially life-threatening hypotension and even aggravating angina.

ADME. As outlined previously, nitrovasodilators differ in their dependence on ALDH2 for bioactivation (note ALDH2 deficiency in many Asians). In addition, their pharmacokinetic profiles exhibit therapeutically relevant differences in sublingual resorption, onset of action, and half-life (Table 27–1).

Nitroglycerin. Peak concentrations of GTN are found in plasma within 4 min of sublingual administration; the drug has a t1/2 of about 45 min. The primary initial metabolites, isosorbide-2-mononitrate and ISMN, have longer half-lives (3–6 h) and are presumed to contribute to the therapeutic efficacy of the drug. ISDN is therefore suitable both for standby and sustained therapy.

Isosorbide Dinitrate. Sublingual administration of ISDN produces maximal plasma concentrations of the drug by 6 min, and the fall in concentration is rapid (t1/2 of about 45 min). The primary initial metabolites, isosorbide-2-mononitrate and ISMN, have longer half-lives (3–6 h) and are presumed to contribute to the therapeutic efficacy of the drug. ISDN is therefore suitable both for standby and sustained therapy.

Isosorbide-5-Mononitrate. This agent is available in tablet form. ISMN does not undergo significant first-pass metabolism, so it has high bioavailability after oral administration, but its onset of action is too slow for acute treatment of angina.

Inhaled NO. Nitric oxide gas administered by inhalation appears to exert most of its therapeutic effects on the pulmonary vasculature because of the rapid inactivation of NO by hemoglobin in the blood. It is approved for the treatment of pulmonary hypertension in hypoxic neonates, where it reduced morbidity and mortality (Bloch et al., 2007), and is currently tested in patients with pulmonary arterial hypertension.
Mechanisms of Antianginal Efficacy of Organic Nitrates

When GTN is injected directly into the coronary circulation of patients with CAD, anginal attacks (induced by electrical pacing) are not aborted even when coronary blood flow is increased. In contrast, sublingual administration of GTN does relieve anginal pain in the same patients, indicating that the major antianginal effect of nitrovasodilators is mediated by preload reduction rather than coronary artery dilation.

This interpretation is supported by studies in exercising patients showing that angina occurs at the same value of the triple product (Aortic pressure × Heart rate × Ejction time, which is roughly proportional to myocardial consumption of O₂) with or without nitroglycerin. Thus, the beneficial effect of nitroglycerin has to result from reduced cardiac O₂ demand rather than an increase in the delivery of O₂ to ischemic regions of myocardium. However, these results do not preclude the possibility that a favorable redistribution of blood flow to ischemic subendocardial myocardium may contribute to relief of pain in a typical anginal attack, and they do not preclude the possibility that direct coronary vasodilation may be the major effect of nitroglycerin in situations where vasospasm compromises myocardial blood flow.

Effects on Myocardial O₂ Requirements. The major determinants of myocardial O₂ consumption are left ventricular wall tension, heart rate, and myocardial contractility (Figure 27–1). Ventricular wall tension is affected by preload and afterload. Preload is determined by the diastolic pressure that distends the ventricle (ventricular end-diastolic pressure). Increasing end-diastolic volume augments the ventricular wall tension (by the law of Laplace, tension is proportional to pressure times radius). Increasing venous capacitance with nitrates decreases venous return to the heart, decreases ventricular end-diastolic volume, and thereby decreases O₂ consumption. An additional benefit of reducing preload is that it increases the pressure gradient for perfusion across the ventricular wall, which favors subendocardial perfusion. Afterload is the impedance against which the ventricle must eject. In the absence of aortic valvular disease, afterload is related to peripheral resistance. Decreasing peripheral arteriolar resistance reduces afterload and thus myocardial work and O₂ consumption. The distensibility of the large conductance arteries such as the aorta may play an additional role.

Nitrovasodilators preferentially decrease preload by dilating venous capacitance vessels. The decrease in afterload is generally small and mainly observed at higher doses. The effect on aortic stiffness appears complex (Soma et al., 2000). NO and nitrovasodilators can directly modulate the inotropic or chronotropic state of the heart via cGMP and its stimulatory effect on PDE2 (thereby reducing cAMP) or an inhibitory effect on the cAMP-specific PDE3 (thereby increasing cAMP). An inotropic response depends on the extent to which the PDE isoforms are expressed in the appropriate cells and in the proper subcellular compartment (Steinberg and Brunton, 2001). Small NO concentrations favor a positive inotropic effect (Koja et al., 1997); however, the effect size is small and its significance unclear. Because nitrates affect several of the primary determinants of myocardial O₂ demand, their net effect usually is to decrease myocardial O₂ consumption. In addition, an improvement in the lusitropic state of the heart may be seen with more rapid early diastolic filling. This may be secondary to the relief of ischemia rather than primary, or it may be due to a reflex increase in sympathetic activity. Nitrovasodilators also increase CGMP in platelets, with consequent inhibition of platelet function. While this may contribute to their antiangiinal efficacy, the effect appears to be modest and in some settings may be counterbalanced by the potential of nitrates to alter the pharmacokinetics of heparin, reducing its antithrombotic effect.

Effects on Total and Regional Coronary Blood Flow. When considering the effect of vasodilators in the ischemic heart, it is important to realize that myocardial ischemia itself is a powerful stimulus to coronary vasodilation and part of an autoregulatory mechanism. In the presence of atherosclerotic coronary artery narrowing, ischemia distal to the lesion stimulates vasodilation of downstream resistance arterioles and thereby helps maintain adequate perfusion of the ischemic area under rest. If the stenosis is severe, much of the capacity to dilate is used to maintain resting blood flow. Further dilation may not be possible, neither under exercise nor with therapeutically applied vasodilators. In contrast, nonselective vasodilators such as adenosine or dipyridamole (which inhibits adenosine transmembrane transport and thereby increases extracellular concentrations) can worsen the perfusion of ischemic areas by dilating the relatively constricted arterioles of the healthy myocardium, leading to redistribution of blood flow away from the ischemic myocardium (“steal phenomenon”). Accordingly, dipyridamole is not used therapeutically but can be used as a stress test to provoke angina pectoris (Bodi et al., 2007).

Nitrovasodilators, in contrast, do not have a major effect on the smaller resistance arteries (and therefore do not cause steal phenomena) but can dilate the large, epicardial sections of the coronary arteries upstream of a stenosis and also in a stenosis (concept of the “dynamic stenosis”; Brown et al., 1981) and thereby increase blood flow distal to the narrowing. Collateral flow to ischemic regions also is increased. As outlined previously, GTN also reduces wall stress that opposes blood flow to the subendocardium, which is particularly sensitive to ischemia.

In patients with angina owing to coronary artery spasm, the capacity of nitrovasodilators to dilate epicardial coronary arteries, particularly regions affected by spasm, is the primary mechanism of their beneficial effect.

Other Effects. The nitrovasodilators also relax smooth muscles of the bronchial tract, the gallbladder, biliary ducts, and sphincter of Oddi and the GI tract. Spontaneous mortality decreased by nitrates both in vivo and in vitro. The effect may be transient and incomplete in vivo, but abnormal “spasm” frequently is reduced. Indeed, many incidences of atypical chest pain and “angina” are due to biliary or esophageal spasm, and these also can be relieved by nitrates. Nitrates can also relax ureteral and uterine smooth muscle, but these responses are of uncertain clinical significance.

Tolerance

Frequently repeated or continuous exposure to high doses of nitrovasodilators lead to tolerance, that is, marked attenuation in the magnitude of most of their pharmacological effects. The magnitude of tolerance is a function of dosage and frequency of use. Tolerance may result from a reduced capacity of the vascular smooth muscle to convert nitroglycerin to NO, true vascular tolerance, or to the activation of mechanisms extraneous to the vessel wall, pseudotolerance (Munzel et al., 1995). Multiple mechanisms have been proposed to account for nitrate tolerance, including volume expansion, neurohumoral activation, cellular depletion of sulphhydryl groups, and the generation of free radicals (Parker and Parker, 1998). A reactive intermediate formed during the generation of NO from organic nitrates may itself damage and inactivate the enzymes of the activation pathway (Munzel et al., 1995; Parker, 2004). Inactivation of ALDH2 (Sydow et al., 2004) and S-nitrosylation of soluble guanylyl cyclase (Sayed et al., 2008) are seen in models of nitrate tolerance and could explain cross-tolerance to different (nitro)vasodilators. Other changes observed in the setting of nitroglycerin tolerance include an enhanced response to vasoconstrictors such as angiotensin II, serotonin, and phenylephrine. Prolonged administration of GTN is associated with plasma volume expansion, which may be reflected by a decrease in hematocrit. Unfortunately, attempts to prevent nitrate tolerance based on these mechanisms (e.g., antioxidants, coapplication of vasodilators or diuretics) failed in clinical trials.

A clinically important lesson of research on nitrate tolerance is that prolonged treatment with nitrates may not only induce a loss of response to nitrates, but also actually decrease angina threshold in the interval (Parker et al., 1995). A special form of GTN tolerance is observed in individuals exposed to GTN in the manufacture of explosives. If protection is inadequate, workers may experience severe headaches, dizziness, and postural weakness during the first several days of employment (“Monday disease”). Tolerance then develops and can lead to organic nitrate dependence. Workers without demonstrable organic vascular disease have been reported to have an increase in the incidence of ACSs during the 24- to 72-h period of downstream effects away from the work environment. It seems prudent not to withdraw nitrates abruptly from a patient who has received such therapy chronically.
therapy should be designed to prevent tolerance. High doses should be avoided and therapy interrupted for 8–12 h daily, which allows the return of efficacy. In patients with exertional angina, it is usually most convenient to omit dosing at night either by adjusting dosing intervals of oral or buccal preparations or by removing cutaneous GTN. Patients whose anginal pattern suggests its precipitation by increased left ventricular filling pressures (e.g., in association with orthopnea or paroxysmal nocturnal dyspnea) may benefit from continuing nitrates at night and omitting them during a quiet period of the day. Some patients develop an increased frequency of nocturnal angina when a nitrate-free interval is employed using GTN patches; such patients may require another class of antianginal agent during this period. Continuous intravenous administration of GTN regularly induces tolerance and should therefore be avoided. Tolerance also has been seen with ISMN and ISDN; an eccentric twice-daily dosing schedule appears to maintain efficacy (Parker and Parker, 1998). Molsidomine, a direct NO donor, is approved in many European countries and is claimed to induce less tolerance than the organic nitrates, but the supporting evidence is weak. A recent study failed to demonstrate beneficial effects of molsidomine on endothelial dysfunction (Barbato et al., 2015).

Toxicity and Untoward Responses
Untoward responses to the therapeutic use of organic nitrates are almost all secondary to actions on the cardiovascular system. Headache is common and can be severe, usually decreasing over a few days if treatment is continued and often controlled by decreasing the dose. Transient episodes of dizziness, weakness, and other manifestations associated with postural hypotension may develop, particularly if the patient is standing immobile, and may progress occasionally to loss of consciousness, a reaction that appears to be accentuated by alcohol. It also may be seen with very low doses of nitrates in patients with autonomic dysfunction. Even in severe nitrate syncope, positioning and other measures that facilitate venous return are the only therapeutic measures required. All the organic nitrates occasionally can produce drug rash.

Interaction of Nitrates With PDE5 Inhibitors.
Erectile dysfunction is a frequently encountered problem whose risk factors parallel those of CAD. Thus, many men desiring therapy for erectile dysfunction already may be receiving (or may require, especially if they increase physical activity) antianginal therapy. The combination of sildenafil and other PDE5 inhibitors with organic nitrate vasodilators can cause extreme hypotension.

Cells in the corpus cavernosum produce NO during sexual arousal in response to nonadrenergic, noncholinergic neurotransmission (Burnett et al., 1992). NO stimulates the formation of cGMP, which leads to relaxation of smooth muscle of penile arteries that fill the corpus cavernosum, leading to engorgement of the corpus cavernosum and erection. The accumulation of cGMP is enhanced by inhibition of the cGMP-specific PDE5 family. Sildenafil and congeners inhibit PDE5 and have been demonstrated to improve erectile function in patients with erectile dysfunction. Not surprisingly, PDE5 inhibitors have assumed the status of widely used recreational drugs. Sildenafil is also FDA and EMA approved in patients with pulmonary arterial hypertension in whom the drug decreased pulmonary vascular resistance and enhanced exercise capacity. PDE5 inhibitors also are being studied in patients with congestive heart failure, but a recent trial in patients with preserved ejection fraction failed (Redfield et al., 2013; Chapter 28). Tadalafil and vardenafl share similar therapeutic efficacy and side-effect profiles with sildenafil; tadalafil has a longer time to onset of action and a longer therapeutic t 1/2 than the other PDE5 inhibitors (Table 45–1). Sildenafil has been the most thoroughly characterized of these compounds, but all three PDE5 inhibitors are contraindicated for patients taking organic nitrate vasodilators, and the PDE5 inhibitors should be used with caution in patients taking α- or β blockers (see Chapter 12).

The side effects of sildenafil and other PDE5 inhibitors are largely predictable on the basis of their effects on PDE5. Headache, flushing, and rhinitis may be observed, as well as dyspepsia owing to relaxation of the lower esophageal sphincter. Sildenafil and vardenafil also weakly inhibit PDE6, the enzyme involved in photoreceptor signal transduction (Figure 69–9), and can produce visual disturbances, most notably changes in the perception of color hue or brightness. In addition to visual disturbances, sudden one-sided hearing loss has also been reported. Tadalafil inhibits PDE11, a widely distributed PDE isoform, but the clinical importance of this effect is not clear. The most important toxicity of all these PDE5 inhibitors is hemodynamic. When given alone to men with severe CAD, these drugs induce only a modest (<10%) decrease of blood pressure (Herrmann et al., 2000). However, PDE5 inhibitors and nitrates act synergistically to cause profound increases in cGMP and dramatic reductions in blood pressure (>25 mm Hg). PDE5 inhibitors should therefore not be prescribed to patients receiving any form of nitrate (Chetlin et al., 1999); in prescribing nitrates, the physician should warn the patient that PDE5 inhibitors and nitrates must not be used concurrently, and that no PDE5 inhibitor should be used in the 24 h prior to initiating nitrate therapy. A period of longer than 24 h may be needed following administration of a PDE5 inhibitor for safe use of nitrates, especially with tadalafil, due to its prolonged t 1/2. In the event that patients develop significant hypotension following combined administration of sildenafil and a nitrate, fluids and a adrenergic receptor agonist, if needed, may be used for support.

Sildenafil, tadalafil, and vardenafl are metabolized via CYP3A4, and their toxicity may be enhanced in patients who receive inhibitors of this enzyme, including macrolide and imidazole antibiotics, and antiretroviral agents (see individual chapters and Chapter 6). PDE5 inhibitors also may prolong cardiac repolarization by blocking the t 1/2. Although these interactions and effects are important clinically, the overall incidence and profile of adverse events observed with PDE5 inhibitors, when used without nitrates, are consistent with the expected background frequency of the same events in the treated population. In patients with CAD whose exercise capacity indicates that sexual activity is unlikely to precipitate angina and who are not currently taking nitrates, the use of PDE5 inhibitors can be considered.
be offered revascularizing therapy. Moreover, chronic treatment with nitrate is not associated with a prognostic benefit and may induce tolerance and endothelial dysfunction as discussed previously. Nitrates must therefore be considered a second choice compared to β blockers. Sustained-release oral preparations of ISDN, ISMN, and GTN are available. Sustained-release ISDN and ISMN are typically given in two doses administered 6–7 h apart, followed by a nitrate-free interval of at least 8 h.

**Variant (Prinzmetal) Angina.** The large coronary arteries normally contribute little to coronary resistance. However, in variant angina, coronary constriction results in reduced blood flow and ischemic pain. Multiple mechanisms have been proposed to initiate vasoospasm, including endothelial cell injury. Whereas long-acting nitrates alone are occasionally efficacious in abolishing episodes of variant angina, additional therapy with Ca²⁺ channel blockers usually is required. Ca²⁺ channel blockers, but not nitrates, have been shown to influence mortality and the incidence of MI favorably in variant angina; they should generally be included in therapy.

**Congestive Heart Failure.** The utility of nitrovasodilators to relieve pulmonary congestion and to increase cardiac output in congestive heart failure is addressed in Chapter 28.

**Unstable Angina Pectoris (Acute Coronary Syndromes, see discussion that follows).** Resistance to nitrates classifies angina symptoms as “unstable” and is a characteristic feature of ACSs, typically caused by transient or permanent thrombotic occlusion of coronary vessels. Nitrates do not modify this process specifically and are second-line drugs.

**Ca²⁺ Channel Blockers**

Voltage-gated Ca²⁺ channels (L-type or slow channels) mediate the entry of extracellular Ca²⁺ into smooth muscle and cardiac myocytes and SA and AV nodal cells in response to electrical depolarization. In both smooth muscle and cardiac myocytes, Ca²⁺ is a trigger for contraction, albeit by different mechanisms. Ca²⁺ channel antagonists, also called Ca²⁺ entry blockers or Ca²⁺ channel blockers, inhibit Ca²⁺ influx. In vascular smooth muscle, this leads to relaxation, especially in arterial beds, in cardiac myocytes to negative inotropic effects. All Ca²⁺ channel blockers exert these two principal actions, but the ratio differs according to the class as does the presence of chronotropic and dromotropic effects.

to contraction of vascular smooth muscle, particularly in some vascular beds. In contrast to cardiac muscle, smooth muscles typically contract tonically. Cytosolic Ca2+ concentrations can be increased by diverse contractile stimuli in vascular smooth muscle cells. Many hormones and autacoids increase Ca2+ influx through so-called receptor-operated channels, whereas increases in external concentrations of K+ and depolarizing electrical stimuli increase Ca2+ influx through voltage-gated, or “potential operated,” channels. The Ca2+ channel blockers produce their effects by binding to the α1 subunit of the L-type voltage-gated Ca2+ channels and reducing Ca2+ flux through the channel. The vascular and cardiac effects of some of the Ca2+ channel blockers are summarized in the next section and in Table 27–2.

Voltage-gated channels contain domains of homologous sequence that are arranged in tandem within a single large subunit. In addition to the major channel-forming subunit (termed α1), Ca2+ channels contain several other associated subunits (termed α2, β, γ, and δ) (Schwartz, 1992). Voltage-gated Ca2+ channels have been divided into at least three subtypes based on their conductances and sensitivities to voltage (Schwartz, 1992; Tsien et al., 1988). The channels best characterized to date are the L, N, and T subtypes. Only the L-type channel is sensitive to the dihydropyridine Ca2+ channel blockers. All approved Ca2+ channel blockers bind to the α1 subunit of the L-type Ca2+ channel, which is the main pore-forming unit of the channel. This approximately 250,000-Da subunit is associated with a disulfide-linked α2δ subunit of about 140,000 Da and a smaller intracellular β subunit. The α1 subunits share a common topology of four homologous domains, each of which is composed of six putative transmembrane segments (S1–S6). The α1, δ, and β subunits modulate the α1 subunit (see Figure 14–2). The phenylalkylamine Ca2+ channel blocker verapamil binds to transmembrane segment 6 of domain IV (IVS6), the benzothiazepine Ca2+ channel blocker diltiazem binds to the cytoplasmic bridge between domain III (IIIIS) and domain IV (IVS), and the dihydropyridine Ca2+ channel blockers (nifedipine and several others) bind to transmembrane segments of both domains III and IV. These three separate receptor sites are linked allosterically.

**Integrated Cardiovascular Effects of Different Ca2+ Channel Antagonists.** The hemodynamic profiles of the Ca2+ channel blockers approved for clinical use differ and depend mainly on the ratio of vasodilating and negative inotropic and chronotropic effects on the heart (Figure 27–2). The dihydropyridines dilate blood vessels at several-fold lower concentrations than those required for decreasing myocardial force; the ratio is close to one for diltiazem and verapamil. The published selectivity values differ widely, depending on the type of blood vessel and the mode of precontraction used for the comparison (Table 27–2 and Figure 27–3). The differences between the relatively vasoselective dihydropyridines and the much less-selective diltiazem and verapamil have important consequences because the decrease in arterial blood pressure elicits reflex sympathetic activation, resulting in the stimulation of heart rate, AV conduction velocity, and myocardial force, just the opposite of the direct effect of Ca2+ channel blockers. While direct and indirect effects normally balance each other in case of verapamil and diltiazem, sympathetic stimulation often prevails in dihydropyridines, causing an increase in heart rate and contractility. Cardiac depressant effects of dihydropyridines may be unmasked, though, in the presence of β blockers and in patients with heart failure.

The dihydropyridines in clinical use—amlodipine, clevidipine, felodipine, isradipine, lercanidipine, nicardipine, nifedipine, nimodipine, and nisoldipine—share most pharmacodynamic properties. Differences with regard to vascular selectivity or subvascular selectivity have been intensely addressed in the past, but claims of large vasoselectivity ratios were based on indirect comparisons (Godfraind et al., 1992). Overall, the clinical relevance of vasoselectivity ratios appears questionable; actual differences are probably not great (Figure 27–3). In any event, the drugs exert their...
antianginal effect mainly by peripheral arterial vasodilation and afterload reduction and not by coronary artery dilation (exception in variant angina).

Verapamil, like the dihydropyridines, causes little effect on venous return and preload, but has more direct negative inotropic and chronotropic effects than the dihydropyridines at doses that produce arteriolar dilation and afterload reduction (Figure 27–2). Thus, the consequences of a reflex increase in adrenergic tone are generally offset by the direct cardiodepressant effects of the drug. In patients without heart failure, oral administration of verapamil reduces peripheral vascular resistance and blood pressure with minimal changes in heart rate. Ventricular performance is not impaired and actually may improve, especially if ischemia limits performance. In contrast, in patients with heart failure, intravenous verapamil can cause a marked decrease in contractility and left ventricular function. The antianginal effect of verapamil, like that of all Ca\(^{2+}\) channel blockers, is due primarily to a reduction in myocardial \(O_2\) demand. The negative dromotropic effect has no relevance for the improvement of exercise but can cause second-degree AV block, particularly when given in combination with \(\beta\) blockers (contraindicated). Diltiazem's effects lie in between those of dihydropyridines and verapamil.

The effects of Ca\(^{2+}\) channel blockers on diastolic ventricular relaxation (the lusitropic state of the ventricle) are complex. Nifedipine, diltiazem, and verapamil impaired parameters of ventricular relaxation in dogs, especially when given into the coronary arteries (Walsh and O'Rourke, 1985). However, reflex stimulation of sympathetic tone accelerates relaxation, which may outweigh a direct negative lusitropic effect. Likewise, a reduction in afterload will improve the lusitropic state. In addition, if ischemia is improved, the negative lusitropic effect will be reduced. The sum total of these effects in any given patient cannot be determined a priori.

**ADME and Drug Interactions.** Ca\(^{2+}\) channel blockers exhibit clinically relevant differences in pharmacokinetics (Figure 27–4). Immediate-release nifedipine is quickly absorbed after oral intake and produces only a briefly elevated blood level of the drug (\(t_{1/2} \sim 1.8\) h) that is associated with an

---

**Figure 27–2** Comparison of the integrated actions of Ca\(^{2+}\) channel blockers. Due to different potencies and efficacies at various sites of action within the cardiovascular system, dihydropyridines produce integrated effects that are not identical to those of verapamil and diltiazem. Verapamil can have direct inhibitory effects on the SNS. The thickness of the arrow indicates the relative strength of the effect.

**Figure 27–3** Potency of Ca\(^{2+}\) channel blockers at different sites. Effects were assessed on the contractile force of human right atrial appendages (A) and human arteries from aortic vasa vasorum precontracted with high-K\(^+\) concentrations (B). Felodipine (black), nifedipine (blue), amlodipine (green) are more potent on vascular muscle, inhibiting contraction of atrial muscle at concentrations about 10 times higher than those needed to reduce contraction in vascular tissue. Verapamil (red) inhibits atrial muscle force development at 20% of the concentration required to reduce contraction in vascular tissue. The vascular selectivities of the various Ca\(^{2+}\) channel blockers (EC\(_{50}\) on atrial appendage/EC\(_{50}\) on vasa vasorum) are as follows: felodipine, 12; nifedipine, 7, amlodipine, 5; verapamil, 0.2. (Figure is based on data of Angus et al., 2000.)
CHAPTER 27
TREATMENT OF ISCHEMIC HEART DISEASE

The bioavailability of these drugs may be increased by strong inhibitors of CYP3A4, such as simvastatin and atorvastatin.

Concurrent therapy of a dihydropyridine with a β blocker has proven more effective than either agent given alone in exer
tional angina, presumably because the β blocker suppresses reflex tachycardia. This concurrent drug therapy is particu-
larly attractive because the dihydropyridines do not delay AV conduction and will not enhance the negative dromotropic
effects associated with β receptor blockade. In contrast, the concurrent administration of verapamil or diltiazem with a β blocker is contraindi-
cated for the potential for AV block, severe bradycardia, and decreased
left ventricular function.

The bioavailability of all Ca²⁺ channel blockers is reduced, in some cases markedly, by first-pass metabolism by CYP3A4 enzymes in the intestinal epithelium and the liver. This has two consequences:

- The bioavailability of these drugs may be increased by strong inhibitors of CYP3A4, such as macrolide and imidazole antibiotics, antiretroviral agents, and grapefruit juice (see Chapter 6). Bioavailability is reduced by inducers of CYP3A4, such as rifampin, carbamazepine, and hyper-
icum (St. John’s wort).

- Some Ca²⁺ channel blockers (particularly verapamil) are strong CYP3A4 inhibitors and cause clinically relevant drug interactions with other CYP3A4 substrates, such as simvastatin and atorvastatin.

Moreover, verapamil is a relatively efficient inhibitor of the intestinal and renal ABC transport protein Pgp (also called MDR1 and ABCB1; see Chapter 5) and can thereby increase plasma levels of digoxin, cyclospo-
rine, and loperamide and other agents that are exported by Pgp. This high potential of verapamil for drug-drug interactions is a clear disadvantage and one of the reasons for its declining use. In patients with hepatic cirrhosis, the bioavailability and half-lives of the Ca²⁺ channel blockers may be increased, and dosage should be decreased accordingly. The half-lives of these agents also may be longer in older patients.

Toxicity and Untoward Responses. The profile of adverse reactions to the Ca²⁺ channel blockers varies among the drugs in this class. Immediate-release capsules of nifedipine often cause headache, flushing, and dizzi-
ness and can actually worsen myocardial ischemia. Dizziness and flushing

are much less of a problem with the sustained-release formulations and with the dihydropyridines having a long $t_{1/2}$ and providing more constant plasma drug concentrations. Peripheral edema may occur in some patients with Ca²⁺ channel blockers but is not the result of generalized fluid retention; rather, it most likely results from increased hydrostatic pressure in the lower extremities owing to precapillary dilation and reflex postcapillary constriction (Epstein and Roberts, 2009). Other adverse effects of these drugs are due to actions in nonvascular smooth muscle. For example, Ca²⁺ channel blockers can cause or aggravate gastroesophageal reflux. Constipation is a common side effect of verapamil but occurs less frequently with other Ca²⁺ channel blockers. Urinary retention is a rare adverse effect. Uncommon adverse effects include rash and elevations of liver enzymes.

Although bradycardia, transient asystole, and exacerbation of heart failure have been reported with verapamil, these responses usually have occurred after intravenous administration of verapamil in patients with disease of the SA node, AV nodal conduction disturbances, or in the pres-
ence of β-blockade. The use of intravenous verapamil with an intravenous β blocker is contraindicated because of the increased propensity for AV block or severe depression of ventricular function. Patients with ventric-\nular dysfunction, SA or AV nodal conduction disturbances, and systolic blood pressures below 90 mmHg should not be treated with verapamil or diltiazem, particularly intravenously. Verapamil may also exacerbate AV nodal conduction disturbances observed with digoxin, both for pharma-
codynamic and pharmacokinetic reasons (Pgp inhibition; see previous discussion). When used with quinidine, verapamil may cause excessive hypotension, again due to pharmacodynamic and pharmacokinetic rea-
sons (quinidine is CYP3A4 substrate and Pgp inhibitor).

Therapeutic Uses

Variant Angina. Variant angina results from reduced blood flow (a con-
sequence of transient localized vasoconstriction) rather than increased O₂ demand. Drug-induced causes (e.g., cocaine, amphetamines, suma-
triptan, and related antimigraine drugs) should be excluded. Ca²⁺ channel blockers are effective in about 90% of patients (Montalescot et al., 2013). These agents are considered first-line treatment and may be combined with nitrovasodilators (Amsterdam et al., 2014).

Exertional Angina. Ca²⁺ channel blockers also are effective in the treat-
mament of exertional, or exercise-induced, angina. Numerous double-blind, placebo-controlled studies have shown that these drugs decrease the number of anginal attacks and attenuate exercise-induced ST-segment depression, but evidence for life-prolonging efficacy is lacking. They are therefore considered the drugs of choice if β blockers do not achieve suf-
cient symptomatic benefit or are not tolerated (Montalescot et al., 2013). The Ca²⁺ channel blockers reduce the double product, Heart rate × Sys-
tolic blood pressure, an approximate index of myocardial O₂ demand. Because these agents reduce the level of the double product at a given external workload, and because the value of the double product at peak exercise is not altered, the beneficial effect of Ca²⁺ channel blockers likely derives from a decrease in O₂ demand rather than an increase in coronary flow.

Concurrent therapy of a dihydropyridine with a β blocker has proven more effective than either agent given alone in exertional angina, presum-
ably because the β blocker suppresses reflex tachycardia. This concurrent drug therapy is particularly attractive because the dihydropyridines do not delay AV conduction and will not enhance the negative dromotropic effects associated with β receptor blockade. In contrast, the concurrent administration of verapamil or diltiazem with a β blocker is contraindi-
cated for the potential for AV block, severe bradycardia, and decreased
left ventricular function.

Unstable Angina (Acute Coronary Syndrome). In the past, Ca²⁺ channel blockers were routinely administered in patients presenting with unstable angina and ACS without persistent ST elevation. Reports about trends for harm with immediate-release nifedipine or nifedipine infusion in the absence of β blockers have led to the recommendation not to use dihydropyridines without concurrent therapy with β blockers.
Verapamil and diltiazem are recommended only for patients who continue to show signs of ischemia, do not tolerate β-blockers, have no clinically significant left ventricular dysfunction, and show no signs of disturbed AV conduction (Amsterdam et al., 2014).

Other Uses. The use of verapamil and diltiazem (but not dihydropyridines) as antiarrhythmic agents in supraventricular tachyarrhythmias is discussed in Chapter 30; their use for the treatment of hypertension is discussed in Chapter 28. Ca2+ channel blockers are contraindicated in patients with heart failure with reduced ejection fraction, but amlopidine and felodipine did not worsen the prognosis and can therefore be administered if indicated for other reasons (Chapter 29). Verapamil improves left ventricular outflow obstruction and symptoms in patients with HCM. Diltiazem has shown early promising results in a clinical study in asymptomatic HCM mutation carriers (Ho et al., 2015). Verapamil also has been used in the prophylaxis of migraine headaches but is considered a second-choice drug. Nimodipine has been approved for use in patients with neurological deficits secondary to cerebral vasospasm after the rupture of a congenital intracranial aneurysm, but clinical evidence for greater effectiveness than verapamil or magnesium is sparse. Nifedipine, diltiazem, amlopidine, and felodipine appear to provide symptomatic relief in Raynaud disease. The Ca2+ channel blockers cause relaxation of the myometrium in vitro and may be effective in reducing preterm uterine contractions in preterm labor (see Chapter 44).

β Blockers

β blockers are the only drug class that is effective in reducing the severity and frequency of attacks of exertional angina and in improving survival in patients who have had an MI. They are therefore recommended as first-line treatment of patients with stable CAD (Montalescot et al., 2013) and unstable angina/ACS (Hamm et al., 2011). Recent meta-analyses raised doubts about the mortality-reducing effects of β blockers in the MI reperfusion era (Bangalore et al., 2014); however, some of the results, such as the slightly increased heart failure frequency in patients receiving β blockers, contradicted numerous well-controlled prospective trials (see Chapter 29) and raised doubts about the validity of the analysis. Thus, the issue has not been definitively resolved. β Blockers are not useful for vasospastic angina and, if used in isolation, may worsen that condition. β Blockers appear equally effective in the treatment of exertional angina (Fihn et al., 2012; Montalescot et al., 2013), but very short-acting agents or drug formulations giving rise to large fluctuations of plasma concentrations (e.g., unformulated metoprolol) should be avoided for treatment of chronic CAD.

The effectiveness of β blockers in the treatment of exertional angina is attributable primarily to a fall in myocardial O2 consumption at rest and during exertion. The decrease in myocardial O2 consumption is due to a negative chronotropic effect (particularly during exercise), a negative inotropic effect, and a reduction in arterial blood pressure (particularly systolic pressure) during exercise. A decrease in heart rate prolongs the time of myocardial perfusion during diastole. Moreover, there is evidence that β blockers can increase blood flow toward ischemic regions by increasing coronary collateral resistance and preventing blood from being shunted away from the ischemic myocardium during maximal coronary vasodilation (Billinger et al., 2001), a “reverse steal or Robin Hood phenomenon” (see previous discussion).

Not all actions of β blockers are beneficial in all patients. The decreases in heart rate and contractility cause increases in the systolic ejection period and left ventricular end-diastolic volume; these alterations tend to increase O2 consumption. However, the net effect of β blockade usually is to decrease myocardial O2 consumption, particularly during exercise. Nevertheless, in patients with limited cardiac reserve who are critically dependent on adrenergic stimulation, β blockade can result in profound decreases in left ventricular function. Despite this, several β blockers demonstrably reduce mortality in patients with congestive heart failure, and β blockers have become standard therapy for many such patients (see Chapters 12 and 29).

Numerous β blockers are approved for clinical use. Standard compounds for the treatment of angina are β1-selective and without intrinsic sympathomimetic activity (e.g., atenolol, bisoprolol, or metoprolol). Chapter 12 presents their pharmacology in detail.

Antiplatelet, Anti-integrin, and Antithrombotic Agents

Antiplatelet agents represent the cornerstone of therapy for ACS (Amsterdam et al., 2014; Roffi et al., 2015) and are systematically discussed in Chapter 32. They interfere either with two signaling pathways (TxA2, and ADP) that cooperatively promote platelet aggregation in an auto- and paracrine manner or with a major common pathway of platelet aggregation, the GP IIb/IIIa fibrinogen receptor. Aspirin inhibits platelet aggregation by irreversibly inactivating the thromboxane-synthesizing COX-1 in platelets, thereby reducing production of TxA2. Aspirin, given at doses of 160–325 mg at the onset of treatment of ACS, improves survival (Yeghiazarians et al., 2000). The thienopyridines are ADP receptor (P2Y12 receptor) antagonists that block the proaggregatory effect of ADP, which is stored in vesicles within platelets and released when platelets adhere to prothrombotic structures. The proaggregatory synergism of TxA2 and ADP on platelet aggregation and thrombus formation accounts for the potentiation effect of adding a thienopyridine to aspirin.

The addition of the thienopyridine clopidogrel to aspirin therapy reduces mortality in patients with ACS. Newer thienopyridines (prasugrel, ticagrelor, and cangrelor) with favorable pharmacokinetic properties have been approved for the treatment of ACS. All three appear superior to clopidogrel in treating patients with ACS; contributing factors likely include faster onset of action and less-variable pharmacokinetics. Ticagrelor is a direct, reversible P2Y12 receptor antagonist, while clopidogrel and prasugrel are both prodrugs. The hepatic activation of prasugrel is more stable and faster than that of clopidogrel. Cangrelor is the first P2Y12 receptor antagonist for intravenous application, producing very rapid inhibition of platelet aggregation. Recent guidelines recommend ticagrelor and prasugrel as the primary choice in patients with ACS and clopidogrel as an alternative in patients who cannot receive the former or are on oral anti-coagulation therapy (e.g., for stroke prevention in atrial fibrillation). The place of cangrelor is not yet fully defined (Roffi et al., 2015).

The optimal timing of the initiation of dual platelet treatment is controversial and depends on the likely clinical course. If conservative treatment is likely and the patient is not at an increased risk of bleeding, aspirin and a parenteral anti-coagulant (see discussion that follows) should be given as soon as possible, with the addition of a P2Y12 receptor antagonist as soon as the diagnosis of NSTEMI has been made. Dual platelet inhibition for 1 year is currently recommended for all patients after NSTEMI or STEMI and revascularization, independently of the type of revascularization and type of stent used (Roffi et al., 2015). Due to the irreversible (aspirin, clopidogrel, and prasugrel) or prolonged (ticagrelor) modes of action, the risk of bleeding remains increased for extended periods after withdrawal of these drugs. Nonemergency major noncardiac surgeries should therefore be postponed for 5 (ticagrelor, clopidogrel) or 7 days (prasugrel, aspirin) after intake of the last dose.

Anti-integrin agents directed against the platelet integrin GP IIb/IIIa (including abciximab, tirofiban, and etifibatide) are highly effective by blocking the final effector pathway of platelet aggregation; however, these agents have a small therapeutic index and must be administered parenterally. Meta-analyses of studies in patients with ACS showed that the use of GP IIb/IIIa inhibitors in addition to heparin was associated with about a 10% reduction in mortality, but with an increase in bleeding. Because most of these trials were conducted before the widespread use of the newer and more effective thienopyridines prasugrel and ticagrelor, the current value of the GP IIb/IIIa antagonists is not clear. Guidelines recommend them in patients on prasugrel or ticagrelor only in bailout situations (Roffi et al., 2015).

Heparin, in its unfractionated form and as low-molecular-weight heparin (e.g., enoxaparin), also reduces symptoms and prevents infarction in unstable angina (Yeghiazarians et al., 2000). Fondaparinux, a heparinoid pentasaccharide, antithrombin III-dependent Factor Xa inhibitor has the best efficacy-safety profile of all anticoagulants and is therefore currently
TREATMENT OF ISCHEMIC HEART DISEASE

unchanged drug (5%) and metabolites are excreted in the urine. Ranolazine is metabolized mainly by CYP3A4 and to a lesser extent by CYP2D6; drugs and antipsychotic agents. Coadministration of ranolazine may increase reduction may be needed for other CYP3A4 substrates (e.g., lovastatin), simvastatin and its active metabolite and requiring dose adjustment; dose of CYP3A4 (e.g., rifampin, carbamazepine, and hypericum) can decrease need to be limited when moderate CYP3A4 inhibitors such as verapamil or diltiazem). Ranolazine should not be used together with strong CYP3A4 inhibitors (e.g., P450 3A4 inhibitors, macrolide and imidazole antibiotics, HIV protease inhibitors), and doses have to be considered, but no torsades des pointes arrhythmias or related events have been reported.

Ivabradine

Ivabradine is EMA approved for treating stable angina and heart failure in patients in whom β blockers are not tolerated or are insufficiently effective in reducing heart rate and FDA-approved only for the treatment of heart failure (Chapter 29). Ivabradine is a selective blocker of hyperpolarization-activated HCN ion channels involved in the generation of automaticity in the SA node. By reducing the pacemaker current I fn through HCN channels, the compound dose dependently reduces heart rate and, differently from β blockers, does not affect cardiac contractile force. The antianginal effect is explained solely by reduction of heart rate and thereby O2 demand (Figure 27–1).

A typical, often transient, side effect are phosphenes, transient enhanced lightness in restricted areas of the visual field, that are explained by effects on retinal HCN channels (3%–5% of cases). In a recent study in patients with chronic angina and normal left ventricular function, the addition of ivabradine to β blockers did not confer benefit but was associated with a trend for more cardiovascular end points and an increase in symptomatic bradycardia, atrial fibrillation, and QT prolongation (Fox et al., 2014). The data raise doubts about the hypothesis that heart rate reduction per se is associated with better cardiovascular outcome and has led to restrictions on use of ivabradine (e.g., contraindication for concurrent therapy with verapamil or diltiazem).

Nicroandin

Nicroandin is a nitrate ester of nicotinamide developed as an antianginal agent and currently is approved in many Asian and European countries (but not in the U.S. and Germany) for the treatment of stable angina pectoris. Nicroandin is not available in the U.S.

Mechanism of Action and Pharmacological Effects. Nicroandin has nitrate-like (cGMP-dependent) properties and acts as an agonist at ATP-sensitive potassium (KATP) channels. Its vasodilating action is potentiated by PDE5 inhibitors and only partially blocked by inhibitors of KATP channels, such as glibenclamide, suggesting that both properties participate in nicroandin’s effect. Nicroandin dilates both arterial and venous vascular beds, leading to decreases in afterload and preload of the heart. In the absence of direct effects on contractile force of the ventricles, the decrease in afterload causes cardiac output to increase. The last effect is stronger than that seen after administration of nitrovasodilators and partially explained by (reflex) tachycardia. Thus, the hemodynamic profile of nicroandin lies in between that of nitrovasodilators and dihydropyridine Ca2+ channel blockers. Its antianginal effect is described to be stable, but early studies reported a clear decrease or loss of antianginal effect after 2 weeks of oral treatment (Meany et al., 1989; Rajaratnam et al., 1999).

Experimental and clinical studies indicated that nicroandin has cardio-protective effects (Matsubara et al., 2000), mimicking that of ischemic preconditioning, a phenomenon that short periods of ischemia preceding prolonged stopping of perfusion (as in MI) reduce myocardial injury. While the exact mechanisms are not fully understood, a central role of mitochondrial KATP channels is assumed (Ardehali and O’Rourke, 2005; Sato et al., 2000). Retrospective studies indicated a survival-prolonging effect of chronic treatment with nicroandin in patients with stable CAD, but sufficiently powered prospective studies are lacking.

ADME and Adverse Effects. Nicroandin is rapidly absorbed after sublingual or oral administration and has a short t1/2 (1 h), which does not provide relevant trough levels at the usual regimen of twice-daily dosing at 20 mg/dose. Besides nitrate-like headache and hypotension (note contraindication of concurrent PDE5 inhibitors), nicroandin has been associated with the appearance of ulcersations. They were first described in 1997 (Boulinguez et al., 1997) as large, painful buccal apthosis and seem to extend to a 40%–60% increased risk of GI ulcerations and perforations (Lee et al., 2015).
Trimetazidine

Trimetazidine was developed as an antianginal agent. Its effect is thought to be due to inhibition of long-chain 3-ketoacyl coenzyme A thiolase, the final enzyme in the FFA β-oxidation pathway. This leads to a partial shift from FFA to glucose oxidation in the heart, which provides less ATP but requires less O₂ and may therefore be beneficial in ischemia (Usher et al., 2014). Numerous small studies provided evidence for the efficacy of the compound to reduce angina and increase exercise tolerance, particularly in patients with diabetes and heart failure (e.g., Tuunanen et al., 2008); as with nicorandil, large randomized studies to define the true therapeutic value of this compound are lacking.

Trimetazidine can cause GI upset, nausea, and vomiting, and, rarely, it has been associated with thrombocytopenia, agranulocytosis, and liver dysfunction. More important, trimetazidine may increase the risk of movement disorders such as Parkinson disease, particularly in older patients with decreased kidney function. This serious effect has led to the use of restrictions by the EMA and the recommendation to use trimetazidine only as second-line treatment of stable angina in patients inadequately controlled by or intolerant to first-line antianginal therapies. Trimetazidine is not available in the U.S.

Therapeutic Strategies

Stable Coronary Artery Disease Guidelines

Task forces from the American College of Cardiology and the American Heart Association (Fihn et al., 2012) and the European Society of Cardiology (Montalescot et al., 2013) have published guidelines that are useful in the selection of appropriate initial therapy for patients with chronic stable angina pectoris. All patients with CAD should receive at least one drug for angina relief in addition to fast- and short-acting nitrovasodilators (GTN, ISDN) and, for event prevention, aspirin and a statin. ACEIs should be considered in patients with CAD who have left ventricular dysfunction or diabetes (Table 27–3).

The evidence for clinically relevant differences between the three main classes of antianginal drugs is not compelling. A meta-analysis of publications that compared two or more antianginal therapies concluded that β blockers are associated with fewer episodes of angina per week and a lower rate of withdrawal due to adverse events than is nifedipine. However, differences did not extend to Ca²⁺ channel blockers other than nifedipine. Of note, no significant differences were observed in outcome between long-acting nitrates, Ca²⁺ channel blockers, and β blockers. Nevertheless, guidelines recommend that β blockers be considered first-line treatment of chronic angina relief; Ca²⁺ channel blockers with heart rate–lowering effects (diltiazem, verapamil) are alternatives. Dihydropyridines should be considered in patients who do not tolerate β blockers. In case of persistent angina, a combination of a dihydropyridine and a β blocker should be considered.

Second-Line Treatment

Long-acting organic nitrates/nitrate formulation (e.g., cutaneous GTN) or ranolazine, and, in non-U.S. countries, ivabradine, trimetazidine, and nicorandil may be considered as adjunct therapy in patients whose angina is not adequately controlled by first-line drugs. β Blockers can block the baroreceptor-mediated reflex tachycardia and positive inotropic effects that may occur with nitrates, whereas nitrates, by increasing venous capacitance, can attenuate the increase in left ventricular end-diastolic volume associated with β-blockade. Concurrent administration of nitrates also can alleviate the increase in coronary vascular resistance associated with blockade of β adrenergic receptors. Ranolazine and trimetazidine have a direct effect on the myocardium and likely act independently of hemodynamic effects. They can therefore be well combined with all other antianginal drugs where permitted. Ivabradine is a possible alternative to β blockers but is associated with toxicity when added to β blockers, verapamil, or diltiazem (Fox et al., 2014).

Ca²⁺ Channel Blockers and Nitrates. In severe exertional or vasospastic angina, the combination of a nitrate and a Ca²⁺ channel blocker may provide additional relief over that obtained with either type of agent alone. Because nitrates primarily reduce preload, whereas Ca²⁺ channel blockers reduce afterload, the net effect on reduction of O₂ demand should be additive; however, excessive vasodilation and hypotension can occur.

Acute Coronary Syndromes

The term ACS refers to chest pain with or without MI (i.e., myocardial necrosis). The latter diagnosis is essentially based on the presence or absence of increases in plasma levels of cardiac troponin (I or T). With tests becoming more and more sensitive, the number of MI diagnoses has increased, while that of unstable angina (i.e., chest pain without necrosis) has decreased. The term unstable angina pectoris is used for angina symptoms that present for the first time, change their usual pattern, occur at rest, or are resistant to nitrates.

Common to most clinical presentations of ACS is a disruption of a coronary plaque, leading to local platelet aggregation and thrombosis at the arterial wall, with subsequent partial or total occlusion of the vessel. Less commonly, vasospasm in minimally atherosclerotic coronary vessels

CHAPTER 27
TREATMENT OF ISCHEMIC HEART DISEASE

• Antiplatelet agents, including aspirin and thienopyridines (e.g., clopidogrel, prasugrel, or ticagrelor)
• Antithrombin agents such as heparin or fondaparinux
• Primary angioplasty with percutaneously deployed intracoronary stents or, if not possible for logistical reasons, fibrinolysis with t-PA
• Coronary bypass surgery for selected patients

The β blockers reduce O2 consumption and arrhythmias and have been associated with a moderate reduction in mortality in ACS but should be avoided in patients with compromised ventricular function or decreased blood pressure (Roffi et al., 2015). Nitrates are useful in reducing vaso-
spasm and in reducing myocardial O2 consumption by decreasing ventric-
ular wall stress. Intravenous administration of nitroglycerin allows high concentrations of drug to be attained rapidly. Because nitroglycerin is degraded rapidly, the dose can be titrated quickly and safely using intrave-
nous administration. If coronary vasoconstriction is present, intravenous nitro-
glycerin is likely to be effective, although the addition of a Ca2+ channel blocker may be required to achieve complete control in some patients. If a patient has consumed a PDE5 inhibitor within the preceding 24 h, there is a risk of profound hypotension, and nitrates should be withheld in favor of an alternate antianginal therapy.

While these principles apply to the entire group of patients with ACS, specific treatment algorithms and the value of different drug classes in ACS depend on the exact diagnosis and should be chosen according to recent guidelines (Amsterdam et al., 2014; Roffi et al., 2015).

ST-elevation myocardial infarction is generally due to a complete obstruction of a large coronary artery. The mainstay in these patients is immediate reperfusion by primary angioplasty and stenting or, in the absence of invasive options, fibrinolytic therapy.

Non-ST-elevation myocardial infarction can present with variable symptoms and electrocardiographic signs and is likely due to transient obstruction of larger coronary arteries or occlusion of small branches, leading to disseminated myocardial necrosis. Primary angioplasty is also indicated in these patients.

Unstable angina is differentiated from NSTEMI by the absence of increased plasma troponin concentrations. These patients have a better long-term prognosis and benefit less from early invasive procedures and intensified antiplatelet therapy. Mainstays are β blockers and nitro-
vasodilators (in the absence of contraindications such as hypotension). Short-acting Ca2+ channel blockers (e.g., nifedipine; see Figure 27–4) should normally be avoided in ACS because of a strong reflex activation of the sympathetic nervous system, but they are the first choice if vasoconstric-
tion is the underlying cause.

Claudication and Peripheral Vascular Disease

Most patients with peripheral vascular disease also have CAD, and the therapeutic approaches for peripheral and coronary arterial diseases overlap (Rooke et al., 2011). Mortality in patients with peripheral vascular disease is most commonly due to cardiovascular disease (Regensteiner and Hiatt, 2002), and treatment of CAD remains the central focus of therapy. Many patients with advanced peripheral arterial disease are more limited by the consequences of peripheral ischemia than by myocardial ischemia. In the cerebral circulation, arterial disease may be manifest as stroke or transient ischemic attacks. The painful symptoms of peripheral arterial disease in the lower extremities (claudication) typically are provoked by exertion, with increases in skeletal muscle O2 demand exceeding blood flow that is impaired by proximal stenoses. When flow to the extremities becomes critically limiting, peripheral ulcers and rest pain from tissue ischemia can become debilitating.

Most of the therapies shown to be efficacious for treatment of CAD also have a salutary effect on progression of peripheral artery disease (Hirsch et al., 2006). Antiplatelet therapy using aspirin (75–325 mg) and clopi-
dogrel (75 mg) are recommended, although the evidence for benefi-
cial effects on cardiovascular or total mortality are mixed (Rooke et al., 2011). Oral anticoagulation is ineffective and increases bleeding risks. ACEIs and statins have been recommended for patients with peripheral artery disease (Hirsch et al., 2006), but the evidence for prognostic benefits is much weaker than in CAD. Interestingly, neither intensive treatment of diabetes mellitus nor antihypertensive therapy appears to alter the progression of symptoms of claudication, although lifestyle modifications remain cornerstones of therapy for patients with claudication; physical exercise, rehabilitation, and smoking cessation (possibly supported by drug treatment with varenicline or bupropion) have proven efficacy.

Drugs used specifically in the treatment of lower extremity claudication include pentoxifylline and cilostazol. Pentoxifylline is a methylxanthine derivative that is called a "theologic modifier" for its effects on increasing the deformability of red blood cells. However, the effects of pentoxifylline on lower extremity claudication appear to be modest and not sufficiently supported by prospective evidence (Salihiyah et al., 2015).

Cilostazol is an inhibitor of PDE3 and promotes accumulation of intracellular CAMP in many cells, including blood platelets. Cilostazol-mediated increases in CAMP inhibit platelet aggregation and promote vasodilation. The drug is metabolized by CYP3A4 and has important drug interactions with other drugs metabolized via this pathway (see Chapter 6). Cilostazol has been mainly studied in Asian populations and seems to improve symptoms of claudication, but the effect on cardiovascu-
lar mortality remains unclear (Bedenis et al., 2014). As a PDE3 inhibitor, cilostazol is in the same drug class as milrinone, which had been used orally as an inotropic agent for patients with heart failure. Milrinone ther-
apy was associated with an increase in sudden cardiac death, and the oral form of the drug was withdrawn from the market. Concerns about several other inhibitors of PDE3 (inamrinone, flosequinar) followed. Cilostazol therefore is labeled as being contraindicated in patients with heart failure, although it is not clear that cilostazol itself leads to increased mortality in such patients. Cilostazol has been reported to increase nonsustained ventricular tachycardia; headache is the most common side effect.

Other treatments for claudication, including naftidrofuryl, propio-
ynyl levocarnitine, and prostaglandins, have been explored in clinical trials, and there is some evidence that some of these therapies may be efficacious.

Mechanopharmacological Therapy: Drug-Eluting Endovascular Stents

Intracoronary stents can ameliorate angina and reduce adverse events in patients with ACSs. However, the long-term efficacy of intracoronary stents is limited by subacute luminal restenosis within the stent, which, in bare metal stents, occurs in 20%–30% of patients during the first 6–9 months of follow-up (Montalescot et al., 2013). The pathways that lead to “in-stent restenosis” are complex, but smooth muscle proliferation within the lumen of the stented artery is a common pathological finding. Local antiproliferative therapies at the time of stenting have been explored over many years; several drug-eluting stents and, more recently, biodegrad-
able stents have been introduced in the market. The drugs currently used in intravascular stents are paclitaxel, sirolimus (rapamycin), and the two sirolimus derivatives everolimus and zotarolimus. Paclitaxel is a tricyclic diterpene that inhibits cellular proliferation by binding to and stabilizing polymerized microtubules. Sirolimus is a hydrophobic macrolide that binds to the cytosolic immunophilin FKBP12; the FKBP12-sirolimus complex inhibits the protein kinase mTOR, the mammalian target of rapamycin (see Figure 35–2), thereby inhibiting cell cycle progression (Figure 65–2). Paclitaxel and sirolimus differ markedly in their mecha-

Brunton_Chi27_p0489-p0506.indd 502
08/09/17 5:46 PM
layer can lead to thrombosis. The inhibition of cellular proliferation by paclitaxel and sirolimus or derivatives not only affects vascular smooth muscle cell proliferation but also attenuates the formation of an intact endothelial layer within the stented artery and thereby markedly reduces the rate of restenosis compared with bare metal stents. Dual antiplatelet therapy (aspirin, typically with clopidogrel) is recommended for one year after intracoronary stenting with drug-eluting stents, similar to bare metal stents. Evidence for the benefit of even longer periods is limited.

Bibliography

Hypertension is the most common cardiovascular disease. Elevated arterial pressure causes hypertrophy of the left ventricle and pathological changes in the vasculature. As a consequence, hypertension is the principal cause of stroke; a major risk factor for CAD and its attendant complications, MI and sudden cardiac death; and a major contributor to heart failure, renal insufficiency, and dissecting aneurysm of the aorta. The prevalence of hypertension increases with age; for example, about 50% of people between the ages of 60 and 69 years old have hypertension, and the prevalence further increases beyond age 70. According to a recent survey in the U.S., 81.5% of those with hypertension are aware they have it, 74.9% are being treated, yet only 52.5% are considered controlled (Go et al., 2014). The success of hypertension treatment programs, such as one organized in a large integrated healthcare delivery system in the U.S. (Jaffe et al., 2013), show that these figures can be substantially improved by electronic hypertension registries tracking hypertension control rates, regular feedback to providers, development and frequent updating of an evidence-based treatment guideline, promotion of single-pill combination therapies, and follow-up blood pressure checks. Between 2001 and 2009, this program increased the number of patients with a diagnosis of hypertension by 78%, as well as the proportion of subjects meeting target blood pressure goals from 44% to more than 84% (Jaffe et al., 2013).

Hypertension is defined as a sustained increase in blood pressure of 140/90 mmHg or higher, a criterion that characterizes a group of patients whose risk of hypertension-related cardiovascular disease is high enough to merit medical attention. Actually, the risk of both fatal and nonfatal cardiovascular disease in adults is lowest with systolic blood pressures of less than 120 mmHg and diastolic blood pressures less than 80 mmHg; these risks increase incrementally as systolic and diastolic blood pressures rise. Recognition of this continuously increasing risk prevents a simple definition of hypertension (Go et al., 2014) (Table 28–1). Although many of the clinical trials classified the severity of hypertension by diastolic pressure, progressive elevations of systolic pressure are similarly predictive of adverse cardiovascular events; at every level of diastolic pressure, risks are greater with higher levels of systolic blood pressure. Indeed, in patients more than 50 years old, systolic blood pressures predict adverse outcomes better than do diastolic pressures. Pulse pressure, defined as the difference between systolic and diastolic pressure, may add additional predictive value (Pastor-Barriuso et al., 2003). This may be at least in part due to higher-than-normal pulse pressure indicating adverse remodeling of blood vessels, representing an accelerated decrease in blood vessel compliance normally associated with aging and atherosclerosis. Isolated systolic hypertension (sometimes defined as systolic blood pressure greater than 140–160 mmHg with diastolic blood pressure less than 90 mmHg) is largely confined to people older than 60 years.

The presence of pathological changes in certain target organs heralds a worse prognosis than the same level of blood pressure in a patient lacking these findings. For instance, retinal hemorrhages, exudates, and papilledema in the eyes indicate a far worse short-term prognosis for a given level of blood pressure. Left ventricular hypertrophy defined by electrocardiogram, or more sensitively by echocardiography or cardiac magnetic resonance imaging, is associated with a substantially worse long-term outcome that includes a higher risk of sudden cardiac death. The risk of cardiovascular disease, disability, and death in hypertensive patients also is increased markedly by concomitant cigarette smoking, diabetes, or elevated LDL; the coexistence of hypertension with these risk factors increases cardiovascular morbidity and mortality to a degree that is compounded by each additional risk factor.

The purpose of treating hypertension is to decrease cardiovascular risk; thus, other dietary and pharmacological interventions may be required to treat these additional risk factors. Effective pharmacological treatment of patients with hypertension decreases morbidity and mortality from cardiovascular disease, reducing the risk of strokes, heart failure, and CAD (Rosendorff et al., 2015). The reduction in risk of MI may be less significant.
Principles of Antihypertensive Therapy

Nonpharmacological therapy, or lifestyle-related changes, is an important component of treatment for all patients with hypertension (James et al., 2014; Mancia et al., 2013). In some grade 1 hypertensives (Figure 28–1), nonpharmacological therapy, or lifestyle-related changes, is an important component of treatment of all patients with hypertension (James et al., 2014). Recently, a large comparative study in the group of patients treated with antihypertensives to a systolic blood pressure control (Figure 28–1). Optimal blood pressure goals for drug therapy are still debated, and current guidelines from cardiovascular societies differ slightly (James et al., 2014). Recently, a large comparative study in nondiabetics with increased cardiovascular risk was prematurely stopped because the group of patients treated with antihypertensives to a systolic blood pressure target of 120 mmHg, with an average of 2.8 drugs, experienced a 25% lower rate of cardiovascular end points and total mortality than the group targeted to the current standard goal target of 140 mmHg.

The majority of patients require drug therapy for adequate blood pressure control (Figure 28–1). Optimal blood pressure goals for drug therapy are still debated, and current guidelines from cardiovascular societies differ slightly (James et al., 2014). Recently, a large comparative study in nondiabetics with increased cardiovascular risk was prematurely stopped because the group of patients treated with antihypertensives to a systolic blood pressure target of 120 mmHg, with an average of 2.8 drugs, experienced a 25% lower rate of cardiovascular end points and total mortality than the group targeted to the current standard goal target of 140 mmHg.

(SPRINT Research Group, 2015). The rate of adverse effects such as hypotension and worsening of renal function were higher in the intensified treatment group, yet this did not translate to a signal for real harm. The data will likely lead to a reexamination of current guideline-recommended blood pressure targets.

Arterial pressure is the product of cardiac output and peripheral vascular resistance (Figure 28–2). Drugs lower blood pressure by actions on peripheral resistance, cardiac output, or both. Drugs may decrease the cardiac output by inhibiting myocardial contractility or by decreasing ventricular filling pressure. Reduction in ventricular filling pressure may be achieved by actions on the venous tone or on blood volume via renal effects. Drugs can decrease peripheral resistance by acting on smooth muscle to cause relaxation of resistance vessels or by interfering with the activity of systems that produce constriction of resistance vessels (e.g., the sympathetic nervous system, the RAS). In patients with isolated systolic hypertension, complex hemodynamics in a rigid arterial system contribute to increased blood pressure; drug effects may be mediated not only by changes in peripheral resistance but also via effects on large artery stiffness (Franklin, 2000).

Antihypertensive drugs can be classified according to their sites or mechanisms of action (Table 28–2, Figure 28–2). The hemodynamic consequences of long-term treatment with antihypertensive agents (Table 28–3) provide a rationale for potential complementary effects of concurrent therapy with two or more drugs. Concurrent use of drugs from different classes is a strategy for achieving effective control of blood pressure while minimizing dose-related adverse effects.

It generally is not possible to predict the responses of individuals with hypertension to any specific drug. For example, for some antihypertensive drugs, about two-thirds of patients will have a meaningful clinical response, whereas about one-third of patients will not respond to the same drug. Racial origin and age may have modest influence on the likelihood of a favorable response to a particular class of drugs. Polymorphisms in genes involved in the metabolism of antihypertensive drugs have been identified in the CYPs (phase I metabolism) and in phase II metabolism, such as catechol-O-methyltransferase (see Chapters 6 and 7). While these polymorphisms can change the pharmacokinetics of specific drugs quite markedly (e.g., five times higher plasma concentrations of metoprolol in CYP2D6 poor metabolizers), differences in efficacy are smaller (Rau et al., 2009) and of unknown clinical relevance. Polymorphisms that influence pharmacodynamic responses to antihypertensive drugs, including ACE inhibitors and diuretics, have also been identified, but evidence for clinically meaningful differences in drug response is sparse. Genome-wide scanning has identified several genetic variants associated with hypertension, but the effect sizes are much smaller than that of clinically established risk factors such as overweight.

Diuretics

An early strategy for the management of hypertension was to alter Na+ balance by restriction of salt in the diet. Pharmacological alteration of Na+ balance became practical with the development of the orally active thiazide diuretics (see Chapter 25). These and related diuretic agents have

Abbreviations

**ACE:** angiotensin-converting enzyme  
**ACEI:** angiotensin-converting enzyme inhibitor  
**Aldo:** aldosterone  
**AngII:** angiotensin II  
**ANP:** atrial natriuretic peptide  
**ARB:** angiotensin receptor blocker  
**AT1:** type 1 receptor for angiotensin II

antihypertensive effects when used alone, and they enhance the efficacy of virtually all other antihypertensive drugs. Thus, this class of drugs remains important in the treatment of hypertension.

The exact mechanism for reduction of arterial blood pressure by diuretics is not certain. The initial action of thiazide diuretics decreases extracellular volume by interacting with a thiazide-sensitive NCC (SLC12A3) expressed in the distal convoluted tubule in the kidney, enhancing Na⁺ excretion in the urine, and leading to a decrease in cardiac output. However, the hypotensive effect is maintained during long-term therapy due to decreased vascular resistance; cardiac output returns to pretreatment values, and extracellular volume returns to almost normal due to compensatory responses such as activation of the RAS. The long-term vasodilation induced by thiazide diuretics is unknown. Hydrochlorothiazide may open Ca²⁺-activated K⁺ channels, leading to hyperpolarization of vascular smooth muscle cells, which leads in turn to closing of L-type Ca²⁺ channels and lower probability of opening, resulting in decreased Ca²⁺ entry and reduced vasoconstriction. Hydrochlorothiazide also inhibits vascular carbonic anhydrase, which, hypothetically, could alter smooth muscle cell systolic pH and thereby cause opening of Ca²⁺-activated K⁺ channels with the consequences noted previously.

The relevance of these findings—largely assessed in vitro—to the observed antihypertensive effects of thiazides is speculative. The major action of these drugs on SLC12A3—expressed predominantly in the distal convoluted tubules and not in vascular smooth muscle or the heart—suggests that these drugs decrease peripheral resistance as an indirect effect of negative Na⁺ balance. That thiazides lose efficacy in treating hypertension in patients with coexisting renal insufficiency is compatible with this hypothesis. Moreover, carriers of rare functional mutations in SLC12A3 that decrease renal Na⁺ reabsorption have lower blood pressure than appropriate controls (Ji et al., 2008); in a sense, this is an experiment of nature that may mimic the therapeutic effect of thiazides.

Benzothiadiazines and Related Compounds

Benzothiadiazines ("thiazides") and related diuretics are the most frequently used class of antihypertensive agents in the U.S. Following the discovery of chlorothiazide, a number of oral diuretics were developed that have an arylsulfonamide structure and block the NCC. Some of these are not benzothiadiazines but have structural features and molecular functions that are similar to the original benzothiadiazine compounds; consequently, they are designated as members of the thiazide class of diuretics. For example, chlorthalidone (also written as chlortalidone), one of the nonbenzothiadiazines, is widely used in the treatment of hypertension, as is indapamide.

Regimen for Administration of the Thiazide-Class Diuretics in Hypertension

Because members of the thiazide class have similar pharmacological effects, they generally have been viewed as interchangeable with appropriate
adjustment of dosage (see Chapter 25). However, the pharmacokinetics and pharmacodynamics of these drugs differ, so they may not necessarily have the same clinical efficacy in treating hypertension. In a direct comparison, the antihypertensive efficacy of chlorthalidone was greater than that of hydrochlorothiazide, particularly during the night (Ernst et al., 2006), suggesting the much longer 1/2 of chlorthalidone (>24 h) compared to hydrochlorothiazide (several hours) gave more stable blood pressure reductions. In light of the considerable clinical trial data supporting the capacity of chlorthalidone to diminish adverse cardiovascular events—in comparison to that available for currently used low doses of hydrochlorothiazide—there is a growing concern that chlorthalidone may be an underutilized drug in hypertensive patients requiring a diuretic.

Antihypertensive effects can be achieved in many patients with as little as 12.5 mg daily of chlorthalidone or hydrochlorothiazide. Furthermore, when used as monotherapy, the maximal daily dose of thiazide-class diuretics usually should not exceed 25 mg of hydrochlorothiazide or chlorthalidone (or equivalent). Even though more diuresis can be achieved with higher doses, some evidence suggests that doses higher than this are not generally more efficacious in lowering blood pressure in patients with normal renal function. Low doses of either chlorthalidone or hydrochlorothiazide—particularly during the night (Ernst et al., 2006)—gave more stable blood pressure reductions. In light of the considerable clinical trial data supporting the capacity of chlorthalidone to diminish adverse cardiovascular events—in comparison to that available for currently used low doses of hydrochlorothiazide—there is a growing concern that chlorthalidone may be an underutilized drug in hypertensive patients requiring a diuretic.

Inadequate diuretic-induced loss of K⁺ can be a problem with thiazides. ACE inhibitors and ARBs will attenuate diuretic-induced loss of K⁺ to some degree. hence a consideration if a second drug is required to achieve further blood pressure reduction beyond that attained with the diuretics alone. Because the pyeloperi nephric effects of these drugs are greatly enhanced when they are given in combination, care should be taken to initiate combination therapy with low doses of each of these drugs (Vlasses et al., 1983). Administration of ACE inhibitors or ARBs together with other
K+-sparing agents or with K+ supplements requires great caution; combining K+-sparing agents with each other or with K+ supplementation can cause potentially dangerous hyperkalemia in some patients.

In contrast to the limitation on the dose of thiazide-class diuretics used as monotherapy, the treatment of severe hypertension that is unresponsive to three or more drugs may require larger doses of the thiazide-class diuretics. Indeed, hypertensive patients may become refractory to thiazides and related agents: chlorothiazide, chlorothalidone, hydrochlorothiazide, indapamide.

Loop diuretics: bumetanide, furosemide, torsemide

K+-sparing diuretics: amiloride, triamterene, MRA spironolactone

Sympatholytic drugs (Chapter 12)

β Blockers: atenolol, bisoprolol, esmolol, metoprolol, nadolol, nebivolol, propranolol, timolol

α Blockers: prazosin, terazosin, doxazosin, phenoxybenzamine

Mixed a/β blockers: labetalol, carvedilol

Centrally acting sympatholytic agents: clonidine, guanabenz, guanfacine, methyldopa, moxonidine, reserpine

Ca++ channel blockers (Chapter 27): amlodipine, clevidipine, diltiazem, felodipine, isradipine, lercanidipine, nicardipine, nifedipine,* nilnidipine, verapamil

Renin-angiotensin antagonists (Chapter 26)

Angiotensin-converting enzyme inhibitors: benazepril, captopril, enalapril, fosinopril, lisinopril, moexipril, perindopril, quinapril, ramipril, trandolapril

AngII receptor blockers: candesartan, eprosartan, irbesartan, losartan, olmesartan, telmisartan, valsartan

Direct renin inhibitor: aliskiren

Vasodilators (Chapters 27 and 28)

Arterial: diazoxide, fenoldopam, hydralazine, minoxidil

Arterial and venous: nitroprusside

*Only extended-release nifedipine is approved for hypertension.

K+ depletion produced by thiazide-class diuretics is dose dependent and variable among individuals, such that a subset of patients may become substantially K+ depleted on diuretic drugs. Given chronically, even small doses lead to some K+ depletion, which is a well-known risk factor for ventricular arrhythmias by reducing cardiac repolarization reserve. The last has recently been used to explain that insults in a particular repolarization current do not necessarily result in QT interval prolongation, the principal clinical measure of repolarization (see Chapter 30). Hypokalemia directly reduces repolarization reserve by decreasing several K+ conductances (inward rectifier I\textsubscript{Kr}, delayed rectifier I\textsubscript{K1}, and the transient outward current I\textsubscript{To}) and increases the binding activity of I\textsubscript{Kr}-inhibiting drugs such as dofetilide (Yang and Roden, 1996). Hypokalemia also reduces the effect of thiazide diuretics is additive with that of other antihypertensive drugs, combination regimens that include these diuretics are common and rational. A wide range of fixed-dose combination products containing a thiazide are marketed for this purpose. Diuretics also have the advantage of minimizing the retention of salt and water that is commonly caused by vasodilators and some sympatholytic drugs. Omitting or underutilizing a diuretic is a frequent cause of “resistant hypertension.”

Adverse Effects and Precautions

The adverse effects of diuretics are discussed in Chapter 25. Some of these determine whether a patient can tolerate and adhere to diuretic treatment.

The K+ depletion produced by thiazide-class diuretics is dose dependent and variable among individuals, such that a subset of patients may become substantially K+ depleted on diuretic drugs. Given chronically, even small doses lead to some K+ depletion, which is a well-known risk factor for ventricular arrhythmias by reducing cardiac repolarization reserve. The last has recently been used to explain that insults in a particular repolarization current do not necessarily result in QT interval prolongation, the principal clinical measure of repolarization (see Chapter 30). Hypokalemia directly reduces repolarization reserve by decreasing several K+ conductances (inward rectifier I\textsubscript{Kr}, delayed rectifier I\textsubscript{K1}, and the transient outward current I\textsubscript{To}) and increases the binding activity of I\textsubscript{Kr}-inhibiting drugs such as dofetilide (Yang and Roden, 1996). *Heart rate can be increased at rest and decreased under exercise as a result of ISA. During rest, ISA may increase resting heart rate; during exercise, β adrenergic antagonism predominates, attenuating heart rate acceleration by NE.
the activity of the Na⁺,K⁺-ATPase (the Na⁺ pump), causing intracellular accumulation of Na⁺ and Ca²⁺, further increasing the risk of afterdepolarizations (Pezhouman et al., 2015). Consequently, hypokalemia increases the risk of drug-induced polymorphic ventricular tachycardia (torsade de pointes; see Chapter 30) and the risk for ischemic ventricular fibrillation, the leading cause of sudden cardiac death and a major contributor to cardiovascular mortality in treated hypertensive patients. There is a positive correlation between diuretic dose and sudden cardiac death and an inverse correlation between the use of adjunctive K⁺-sparking agents and sudden cardiac death (Sisovicv et al., 1994). Thus, hypokalemia needs to be avoided by, for example, combining a thiazide with inhibitors of the RAS or with a K⁺-sparking diuretic.

Thiazides have residual carbonic anhydrase–inhibiting activity, thereby reducing Na⁺ reabsorption in the proximal tubule. The increased presentation of Na⁺ at the macula densa leads to a reduced glomerular filtration rate via tubuloglomerular feedback. While this effect is clinically not meaningful in patients with normal renal function, it reduces diuretic effectiveness and may gain importance in patients with reduced kidney function. RAS inhibitors and Ca²⁺ channel blockers interfere with tubuloglomerular feedback, providing one explanation for the synergistic effect on blood pressure. Erectile dysfunction is a troublesome adverse effect of the thiazide-class diuretics, and physicians should inquire specifically regarding its occurrence in conjunction with treatment with these drugs. Gout may be a consequence of the hyperuricemia induced by these diuretics. The occurrence of either of these adverse effects is a reason for considering alternative approaches to therapy. However, precipitation of acute gout is relatively uncommon with low doses of diuretics. Hydrochlorothiazide may cause rapidly developing, severe hyperonanotremia in some patients. Thiazides inhibit renal Ca²⁺ excretion, occasionally leading to hypercalcemia; although generally mild, this can be more severe in patients subject to hypercalcemia, such as those with primary hyperparathyroidism. The thiazide–induced decreased Ca²⁺ excretion may be used therapeutically in patients with osteoporosis or hypercalcuria.

Thiazide diuretics have also been associated with changes in plasma lipids and glucose tolerance that have led to some concern. The clinical significance of the changes has been disputed because the clinical studies demonstrated comparable efficacy of the thiazide diuretic chlortalidone in reducing cardiovascular risk (ALLHAT Officers, 2002).

All thiazide–like drugs cross the placenta. While they have no direct adverse effects on the fetus, administration of a thiazide during pregnancy increases a risk of transient volume depletion that may result in placental hypoperfusion. Because the thiazides appear in breast milk, they should be avoided by nursing mothers.

Other Diuretic Antihypertensive Agents

The thiazide diuretics are more effective antihypertensive agents than are the loop diuretics, such as furosemide and bumetanide, in patients who have normal renal function. This differential effect is most likely related to the short duration of action of loop diuretics. In fact, a single daily dose of loop diuretics does not cause a significant net loss of Na⁺ for an entire 24-h period because the strong initial diuretic effect is followed by a rebound mediated by activation of the RAS. Unfortunately, loop diuretics are frequently and inappropriately prescribed as a once-a-day medication in the treatment not only of hypertension, but also of congestive heart failure and ascites. The high efficacy of loop diuretics to produce a rapid and profound natriuresis can be detrimental for the treatment of hypertension. When a loop diuretic is given twice daily, the acute diuresis can be excessive and lead to more side effects than occur with a slower-acting, milder thiazide diuretic. Loop diuretics may be particularly useful in patients with azotemia or with severe edema associated with a vasodilator such as minoxidil.

K⁺-Sparking Diuretics

Amiloride and triamterene are K⁺-sparking diuretics that have little value as antihypertensive monotherapy but are important in combination with thiazides to antagonize urinary K⁺ loss and the concomitant risk of ventricular arrhythmias. They act by reversibly inhibiting the ENaC in the distal tubule membrane, the transporter responsible for the reabsorption of Na⁺ in exchange for K⁺. The importance of ENaC for hypertension is illustrated by the fact that an inherited form of hypertension, Liddel syndrome, is due to hyperactivity of ENaC. Gene expression of ENaC is mineralocorticoid sensitive, explaining the antihypertensive and K⁺-sparking effect of another class of K⁺-sparking diuretics, the MRAs spironolactone and eplerenone. In contrast to the immediate and short-term inhibition of ENaC by amiloride and triamterene, the action of MRAs is delayed for about 3 days and is long lasting because MRAs regulate the density of the channel protein in the tubule membrane.

The MRAs have a particular role in hypertension and heart failure (see Chapter 27) because small doses of spironolactone are often highly effective in patients with “resistant hypertension.” First described decades ago (Ramsay et al., 1980), the concept was recently validated in a prospective, placebo-controlled trial comparing spironolactone (25–50 mg) with bisoprolol or doxazosin as add-ons in patients with uncontrolled hypertension despite triple standard antihypertensive therapy (Williams et al., 2015). Spironolactone had about a 2-fold larger blood pressure–lowering effect (8.7 vs. 4.8 and 4 mmHg, respectively). The efficacy of the MRA spironolactone in resistant hypertension supports a primary role of Na⁺ retention in this condition. Some of the effect may be related to the so-called aldosterone-escape phenomenon, or a return to pre-RAS-inhibitor plasma aldosterone levels with extended time of treatment, observed under treatment with RAS inhibitors. Primary hyperaldosteronism occurs in a significant fraction of patients with resistant hypertension (Calhoun et al., 2002).

Spironolactone has some significant adverse effects, especially in men (e.g., erectile dysfunction, gynecomastia, benign prostatic hyperplasia). Eplerenone is a more specific, though less-potent, MRA with reduced side effects.

All K⁺-sparking diuretics should be used cautiously, with frequent measurements of plasma K⁺ concentrations in patients predisposed to hyperkalemia. Patients should be cautioned regarding the possibility that concurrent use of K⁺-containing salt substitutes could produce hyperkalemia. Renal insufficiency is a relative contraindication to the use of K⁺-sparking diuretics. Concomitant use of an ACE inhibitor or an ARB magnifies the risk of hyperkalemia with these agents.

Diuretic-Associated Drug Interactions

Because the antihypertensive effects of diuretics are additive with those of other antihypertensive agents, a diuretic commonly is used in combination with other drugs. The K⁺- and Mg²⁺-depleting effects of the thiazides and loop diuretics can potentiate arrhythmias that arise from digitalis toxicity. Corticosteroids can amplify the hypokalemia produced by the diuretics. NSAIDs (see Chapter 38) that inhibit the synthesis of prostaglandins reduce the antihypertensive effects of diuretics and all other antihypertensives. The renal effects of selective COX-2 inhibitors are similar to those of the traditional NSAIDs. NSAIDs and RAS inhibitors reduce plasma concentrations of aldosterone and can potentiate the hyperkalemic effects of a K⁺-sparking diuretic. All diuretics can decrease the clearance of Li⁺, resulting in increased plasma concentrations of Li⁺ and potential toxicity.

Sympatholytic Agents

With the demonstration in 1940 that bilateral excision of the thoracic sympathetic chain could lower blood pressure, there was a search for effective chemical sympatholytic agents. Many of the early sympatholytic drugs were poorly tolerated and had limiting adverse side effects, particularly on mood. A number of sympatholytic agents are currently in use (Table 28–2). Agonists of α and β adrenergic receptors have been mainstays of antihypertensive therapy.

β Blockers

β Adrenergic receptor antagonists (β blockers) were not expected to have antihypertensive effects when they were first investigated in patients with
angina, their primary indication. However, pronethalol, a drug that was never marketed, was found to reduce arterial blood pressure in hypertensive patients with angina pectoris. This antihypertensive effect was subsequently demonstrated for propranolol and all other β blockers. The basic pharmacology of these drugs is discussed in Chapter 12; characteristics relevant to their use in hypertension are described here.

**Locus and Mechanism of Action**

Antagonism of β adrenergic receptors affects the regulation of the circulation through a number of mechanisms, including a reduction in myocardial contractility and heart rate (i.e., cardiac output; see Figure 27–1). Antagonism of β1 receptors of the juxtaglomerular complex reduces renin secretion and RAS activity. This action likely contributes to the antihypertensive action. Some members of this large, heterogeneous class of drugs have additional effects unrelated to their capacity to bind to β adrenergic receptors. For example, labetalol and carvedilol are also α blockers, and nebivolol promotes endothelial cell–dependent vasodilation via activation of NO production (Pedersen and Cockcroft, 2006) (see Figure 12–4).

**Pharmacodynamic Differences**

The β blockers vary in their selectivity for the β1 receptor subtype, presence of partial agonist or intrinsic sympathomimetic activity, and vasodilating capacity. While all of the β blockers are effective as antihypertensive agents, these differences influence the clinical pharmacology and spectrum of adverse effects of the various drugs. The antihypertensive effect resides in antagonism of the β1 receptor, while major unwanted effects result from antagonism of β2 receptors (e.g., peripheral vasoconstriction, bronchoconstriction, hypoglycemia). Standard therapies are β, blockers without intrinsic sympathomimetic activity (e.g., atenolol, bisoprolol, metoprolol). They produce an initial reduction in cardiac output (mainly β1) and a reflex-induced rise in peripheral resistance, with little or no acute change in arterial pressure. In patients who respond with a reduction in blood pressure, peripheral resistance gradually returns to pretreatment values or less. Generally, persistently reduced cardiac output and possibly decreased peripheral resistance account for the reduction in arterial pressure. Nonselective β blockers (e.g., propranolol) have stronger adverse effects on peripheral vascular resistance by also blocking β2 receptors that normally mediate vasodilation. Vasodilating β blockers (e.g., carvedilol, nebivolol) may be preferred in patients with peripheral artery disease. Drugs with intrinsic sympathomimetic activity (e.g., pindolol, xamoterol) are not recommended for the treatment of hypertension or any other cardiovascular disease because they actually increase nighttime mean heart rate due to their direct partial agonistic activity.

**Pharmacokinetic Differences**

Lipophilic β blockers (metoprolol, bisoprolol, carvedilol, propranolol) appear to have more antithermic efficacy than the hydrophilic compounds (atenolol, nadolol, labetalol), possibly related to a central mode of action. Many β blockers have relatively short plasma half-lives and require more than once-daily dosing (metoprolol, propranolol, carvedilol), a significant disadvantage in the treatment of hypertension. They should generally be prescribed in sustained-release forms. Bisoprolol and nebivolol have t1/2 values of 10–12 h and thus achieve sufficient trough levels at once-daily dosing. Hepatic metabolism of metoprolol, carvedilol, and nebivolol is CYP2D6 dependent. The relevance is probably greatest in case of metoprolol, for which CYP2D6 poor metabolizers (~7% of the Caucasian population) show 5-fold higher drug exposure and 2-fold higher heart rate decreases than the majority of extensive metabolizers (Rau et al., 2009).

**Effectiveness in Hypertension**

Meta-analyses have suggested that β blockers reduce the incidence of MI similar to other antihypertensives but are only about half as effective in preventing stroke (Lindholm et al., 2005). This has led to downgrading of this class of drugs in certain national guidelines (e.g., U.K. standards); however, many of the studies supporting this conclusion were conducted with atenolol, which may not be the ideal β blocker. Atenolol may not lower central (aortic) blood pressure as effectively as it appears when conventionally measured in the brachial artery using a standard arm cuff (Williams et al., 2006). Indeed, atenolol, in contrast to bisoprolol, carvedilol, metoprolol, or nebivolol, has not been positively tested in heart failure trials. Prospective studies of hypertensive agents have not compared different β blockers head to head; therefore, the clinical relevance of pharmacological differences in this heterogeneous drug class remains unclear. Results of a detailed meta-analysis of 147 randomized trials of blood pressure reduction showed that, regardless of blood pressure before treatment, lowering systolic blood pressure by 10 mmHg or diastolic blood pressure by 5 mmHg using any of the main classes of antihypertensive drugs significantly reduced coronary events and stroke without an increase in nonvascular mortality (Law et al., 2009).

**Adverse Effects and Precautions**

The adverse effects of β blockers are discussed in Chapter 12. These drugs should be avoided in patients with reactive airway disease (e.g., asthma) or with SA or AV nodal dysfunction or in combination with other drugs that inhibit AV conduction, such as verapamil. The risk of hypoglycemic reactions may be increased in diabetics taking insulin, but type 2 diabetes is not a contraindication. β Blockers increase concentrations of triglycerides in plasma and lower those of HDL cholesterol without changing total cholesterol concentrations. The long-term consequences of these effects are unknown.

Sudden discontinuation of β blockers can produce a withdrawal syndrome that is likely due to upregulation of β receptors during blockade, causing enhanced tissue sensitivity to endogenous catecholamines—potentially exacerbating the symptoms of CAD. The result, especially in active patients, can be rebound hypertension. Thus, β blockers should not be discontinued abruptly, except under close observation; dosage should be tapered gradually over 10–14 days prior to discontinuation.

**Epinephrine** can produce severe hypertension and bradycardia when a nonselective β blocker is present. The hypertension is due to the unopposed stimulation of a adrenergic receptors when vascular β2 receptors are blocked. The bradycardia is the result of reflex vagal stimulation. Such paradoxical hypertensive responses to β blockers have been observed in patients with hypoglycemia or pheochromocytoma, during withdrawal from clonidine, following administration of epinephrine as a therapeutic agent, or in association with the illicit use of cocaine.

**Therapeutic Uses**

The β blockers provide effective therapy for all grades of hypertension. Marked differences in their pharmacokinetic properties should be considered; once-daily dosing is preferred for better compliance. Populations that tend to have a lesser antihypertensive response to β blockers include the elderly and African Americans. However, intrapatient differences in antihypertensive efficacy are generally much larger than statistical evidence of differences between racial or age-related groups. Consequently, these observations should not discourage the use of these drugs in individual patients in groups reported to be less responsive.

The β blockers usually do not cause retention of salt and water, and administration of a diuretic is not necessary to avoid edema or the development of tolerance. However, diuretics do have additive antihypertensive effects when combined with β blockers. The combination of a β blocker, a diuretic, and a vasodilator is effective for patients who require a third antihypertensive drug. β Blockers (i.e., bisoprolol, carvedilol, metoprolol, or nebivolol) are highly preferred drugs for hypertensive patients with conditions such as MI, ischemic heart disease, or congestive heart failure and may be preferred for younger patients with signs of increased sympathetic drive. However, for other hypertensive patients, particularly older patients with a high risk for stroke, enthusiasm for their early use in treatment has diminished.

**a1 Blockers**

The availability of drugs that selectively block a1 adrenergic receptors without affecting a2 adrenergic receptors adds another group of antihypertensive agents. The pharmacology of these drugs is discussed in detail in Chapter 12. Prazosin, terazosin, and doxazosin are the agents available
for the treatment of hypertension. Phenoxybenzamine, an irreversible α blocker (α1 > α2), is used in the treatment of catecholamine-producing tumors (pheochromocytoma).

**Pharmacological Effects**

Initially, α1 blockers reduce arteriolar resistance and increase venous capacitance; this causes a sympathetically mediated reflex increase in heart rate and plasma renin activity. During long-term therapy, vasoconstriction persists, but cardiac output, heart rate, and plasma renin activity return to normal. Renal blood flow is unchanged during therapy with an α1 blocker. The α1 blockers cause a variable amount of postural hypotension, depending on the plasma volume. Retention of salt and water occurs in many patients during continued administration, and this attenuates the postural hypotension. The α1 blockers reduce plasma concentrations of triglycerides and total LDL cholesterol and increase HDL cholesterol. These potentially favorable effects on lipids persist when a thiazide-type diuretic is given concurrently. The long-term consequences of these small, drug-induced changes in lipids are unknown.

**Therapeutic Uses**

α1 Blockers are not recommended as monotherapy for hypertensive patients, primarily as a consequence of the ALLHAT study (see further discussion). Consequently, they are used primarily in combination with diuretics, β blockers, and other antihypertensive agents. β Blockers enhance the efficacy of α1 blockers. α1 Blockers are not the drugs of choice in patients with pheochromocytoma because a vasoconstrictor response to epinephrine can still result from activation of unblocked vascular α1 adrenergic receptors. α1 Blockers are attractive drugs for hypertensive patients with benign prostatic hyperplasia because they also improve urinary symptoms.

**Adverse Effects**

The use of doxazosin as monotherapy for hypertension increases the risk for developing congestive heart failure (ALLHAT Officers, 2002). This may be a class effect that represents an adverse effect of all of the α1 blockers and has led to recommendations not to use this class of drugs in patients with heart failure. Interpretation of the outcome of the ALLHAT study is controversial, but the commonly held belief that the higher rate of apparent heart failure development in the groups of patients treated with a nondiuretic was caused by withdrawal of prestudy diuretics has not been substantiated (Davis et al., 2006).

A major precaution regarding the use of the α1 blockers for hypertension is the so-called first-dose phenomenon, in which symptomatic orthostatic hypotension occurs within 30–90 min (or longer) of the initial dose of the drug or after a dosage increase. This effect may occur in up to 50% of patients, especially in patients who are already receiving a diuretic. After the first few doses, patients develop a tolerance to this marked hypotensive response.

**Combined α1 and β Blockers**

Carvedilol (see Chapter 12) is a nonselective β blocker with α1-antagonist activity. Carvedilol is approved for the treatment of hypertension and symptomatic heart failure. The ratio of α1 to β-antagonist potency for carvedilol is approximately 1:10. The drug dissociates slowly from its receptor, explaining why the duration of action is longer than the short t½ (2.2 h) and why its effect can hardly be overcome by catecholamines. Carvedilol undergoes oxidative metabolism and glucuronidation in the liver; the oxidative metabolism occurs via CYP2D6. As with labetalol, the long-term efficacy and side effects of carvedilol in hypertension are predictable based on its properties as a β and α1 blocker. Carvedilol reduces mortality in patients with congestive heart failure (Chapter 29). Due to the vasoconstrictor effect, it is a β blocker of choice in patients with peripheral artery disease. Labetalol (see Chapter 12) is an equimolar mixture of four stereoisomers. One isomer is an α1 blocker, another is a nonselective β blocker with partial agonist activity, and the other two isomers are inactive. Labetalol has efficacy and adverse effects that would be expected with any combination of an α1 and β blocker. It has the disadvantages that are inherent in fixed-dose combination products: The extent of α1- to β-blockade is somewhat unpredictable and varies from patient to patient. Labetalol is FDA-approved for eclampsia, preeclampsia, hypertension, and hypertensive emergencies. The main indication for labetalol is hypertension in pregnancy, for which it is one of the few compounds known to be safe (Magee et al., 2016).

**Centrally Acting Sympatholytic Drugs**

**Methyldopa**

Methyldopa, a centrally acting antihypertensive agent, is a prodrug that exerts its antihypertensive action via an active metabolite. Although used frequently as an antihypertensive agent in the past, methyldopa’s adverse effect profile limits its current use largely to treatment of hypertension in pregnancy, where it has a record for safety. Methyldopa (α-methyl-3,4-dihydroxy-L-phenylalanine), an analogue of DOPA, is metabolized by the L-aromatic amino acid decarboxylase in adrenergic neurons to α-methyldopamine, which then is converted to α-methylnorepinephrine, the pharmacologically active metabolite. α-Methylnorepinephrine is stored in the secretory vesicles of adrenergic neurons, substituting for NE, such that the stimulated adrenergic neuron now discharges α-methyldopamine instead of NE. α-Methylnorepinephrine acts in the CNS to inhibit adrenergic neuronal outflow from the brainstem, thereby acting as an agonist at presynaptic α1 adrenergic receptors in the brainstem, attenuating NE release and thereby reducing the output of vasoconstrictor adrenergic signals to the peripheral sympathetic nervous system.

**ADME.** Because methyldopa is a prodrug that is metabolized in the brain to the active form, its t½ has less relevance for its effects than that for many other drugs. Cmax occurs 2–3 h following an oral dose. The drug is eliminated with a t½ of about 21 h. Methyldopa is excreted in the urine primarily as the sulfate conjugate (50%–70%) and as the parent drug (25%). Other minor metabolites include methyldopamine, methylnorepinephrine, and their O-methylated products. The t½ of methyldopa is prolonged to 4–6 h in patients with renal failure.

Despite its rapid absorption and short t½, the peak effect of methyldopa is delayed for 6–8 h, even after intravenous administration, and the duration of action of a single dose is usually about 24 h; this permits once- or twice-daily dosing. The discrepancy between the effects of methyldopa and the measured concentrations of the drug in plasma is most likely related to the time required for transport into the CNS, conversion to the active metabolite storage of α-methyl NE, and its subsequent release in the vicinity of relevant α1 receptors in the CNS. Methyldopa is a good example of a complex relationship between a drug’s pharmacokinetics and its pharmacodynamics. Patients with renal failure are more sensitive to the antihypertensive effect of methyldopa, but it is not known if this is due to alteration in excretion of the drug or to an increase in transport into the CNS.

**Therapeutic Uses.** Methyldopa is a preferred drug for treatment of hypertension during pregnancy based on its effectiveness and safety for both mother and fetus (Magee et al., 2016). The usual initial dose of methyldopa is 250 mg twice daily; there is little additional effect with doses greater than 2 g/d. Administration of a single daily dose of methyldopa at bedtime minimizes sedative effects, but administration twice daily is required for some patients.

**Adverse Effects and Precautions.** Methyldopa produces sedation that is largely transient. A diminution in psychic energy may persist in some patients, and depression occurs occasionally. Methyldopa may produce dryness of the mouth. Other adverse effects include diminished libido, Parkinsonian signs, and hyperprolactinemia that may become sufficiently pronounced to cause gynecomastia and galactorrhea. Methyldopa may precipitate severe bradycardia and sinus arrest.

Methyldopa also produces some adverse effects that are not related to its antihypertensive action in the CNS. Hematotoxicity, sometimes associated with fever, is an uncommon but potentially serious toxic effect of methyldopa. At least 20% of patients who receive methyldopa for a year
develop a positive Coombs test (antiglobulin test) that is due to autoantibodies directed against the Rh antigen on erythrocytes. The development of a positive Coombs test is not necessarily an indication to stop treatment with methyldopa; however, 1%–5% of these patients will develop a hemolytic anemia that requires prompt discontinuation of the drug. The Coombs test may remain positive for as long as a year after discontinuation of methyldopa, but the hemolytic anemia usually resolves within a matter of weeks. Severe hemolysis may be attenuated by treatment with glucocorticoids. Adverse effects that are even rarer include leukopenia, thrombocytopenia, red cell aplasia, lupus erythematosus–like syndrome, lichenoid and granulomatous skin eruptions, myocarditis, retroperiosteal fibrosis, pancreatitis, diarrhea, and malabsorption.

**Clonidine and Moxonidine**

The detailed pharmacology of the α2 adrenergic agonists clonidine and moxonidine is discussed in Chapter 12. These drugs stimulate α2 adrenergic receptors in the brainstem, resulting in a reduction in sympathetic outflow from the CNS (MacMillan et al., 1996). The hypotensive effect correlates directly with the decrease in plasma concentrations of NE. Patients who have had a spinal cord transaction above the level of the sympathetic outflow tracts do not display a hypotensive response to clonidine. At doses higher than those required to stimulate central α2A receptors, these drugs can activate α2B receptors on vascular smooth muscle cells (MacMillan et al., 1996). This effect accounts for the initial vasoconstriction that is seen when overdoses of these drugs are taken and may be responsible for the loss of therapeutic effect that is observed with high doses. A major limitation in the use of these drugs is the paucity of information about their efficacy and adverse effects, and sometimes intolerable adverse effects with these drugs. Sedation and sleep disturbances with vivid dreams or nightmares, restlessness, and depression. Cardiac effects related to the sympatholytic action of these drugs include symptomatic bradycardia and sinus arrest in patients with dysfunction of the SA node and AV block in patients with AV nodal disease or in patients taking other drugs that depress AV conduction. Some 15%–20% of patients who receive transdermal clonidine may develop contact dermatitis.

Sudden discontinuation of clonidine and related α2 adrenergic agonists may cause a withdrawal syndrome consisting of headache, apprehension, tremors, abdominal pain, sweating, and tachycardia. Arterial blood pressure may rise to levels above those present prior to treatment, but the withdrawal syndrome may occur in the absence of an overshoot in pressure. Symptoms typically occur 18–36 h after the drug is stopped and are associated with increased sympathetic discharge, as evidenced by elevated plasma and urine concentrations of catecholamines and metabolites. The frequency of occurrence of the withdrawal syndrome is not known, but withdrawal symptoms are likely dose related and more dangerous in patients with poorly controlled hypertension. Rebound hypertension also has been seen after discontinuation of transdermal administration of clonidine (Metz et al., 1987).

Treatment of the withdrawal syndrome depends on the urgency of reducing the arterial blood pressure. In the absence of life-threatening target organ damage, patients can be treated by restoring the use of clonidine. If a more rapid effect is required, sodium nitroprusside or a combination of an α and β blocker is appropriate. β Blockers should not be used alone in this setting because they may accentuate the hypertension by allowing unopposed a adrenergic vasocostriction caused by activation of the sympathetic nervous system and elevated circulating catecholamines. Because perioperative hypertension has been described in patients in whom clonidine was withdrawn the night before surgery, surgical patients who are being treated with an α2 adrenergic agonist either should be switched to another drug prior to elective surgery or should receive their morning dose or transdermal clonidine prior to the procedure. All patients who receive one of these drugs should be warned of the potential danger of discontinuing the drug abruptly, and patients suspected of being noncompliant with medications should not be given α2 adrenergic agonists for hypertension.

Adverse drug interactions with α2 adrenergic agonists are rare. Diuretics predictably potentiate the hypotensive effect of these drugs. Tricyclic antidepressants may inhibit the antihypertensive effect of clonidine, but the mechanism of this interaction is not known.

**Reserpine**

Reserpine is an alkaloid extracted from the root of Rauwolfia serpentina, a climbing shrub indigenous to India. Ancient Hindu Ayurvedic writings describe medicinal uses of the plant; Sen and Bose described its use in the Indian biomedical literature. However, rauwolfia alkaloids were not used in Western medicine until the mid-1950s. Reserpine was the first drug found to interfere with the function of the sympathetic nervous system in humans, and its use began the modern era of effective pharmacotherapy of hypertension.

**Mechanism of Action.** Reserpine binds tightly to adrenergic storage vesicles in central and peripheral adrenergic neurons and remains bound for prolonged periods of time. The interaction inhibits the vesicular catecholamine transporter VMAT2, so that nerve endings lose their capacity to concentrate and store NE and dopamine. Catecholamines leak into the cytoplasm, where they are metabolized. Consequently, little or no active transmitter is released from nerve endings, resulting in a pharmacological sympathectomy. Recovery of sympathetic function requires synthesis of new storage vesicles, which takes days to weeks after discontinuation of the drug. Because reserpine depletes amines in the CNS as well as in the peripheral adrenergic neuron, it is probable that its antihypertensive effects are related to both central and peripheral actions.

**Pharmacological Effects.** Both cardiac output and peripheral vascular resistance are reduced during long-term therapy with reserpine.
ADME. Few data are available on the pharmacokinetic properties of reserpine because of the lack of an assay capable of detecting low concentrations of the drug or its metabolites. Risperpine that is bound to isolated storage vesicles cannot be removed by dialysis, indicating that the binding is not in equilibrium with the surrounding medium. Because of the irreversible nature of reserpine binding, the amount of drug in plasma is unlikely to bear any consistent relationship to drug concentration at the site of action. Free reserpine is entirely metabolized; therefore, none of the parent drug is excreted unchanged.

Toxicity and Precautions. Most adverse effects of reserpine are due to its effect on the CNS. Sedation and inability to concentrate or perform complex tasks are the most common adverse effects. More serious is the occasional psychotic depression that can lead to suicide. Depression usually appears insidiously over many weeks or months and may not be attributed to the drug because of the delayed and gradual onset of symptoms. Risperpine must be discontinued at the first sign of depression. Risperpine-induced depression may last several months after the drug is discontinued. The risk of depression is likely dose related. Depression is uncommon, but not unknown, with doses of 0.25 mg/d or less. The drug should never be given to patients with a history of depression. Other adverse effects include nasal stuffiness and exacerbation of peptic ulcer disease, which is uncommon with small oral doses.

Therapeutic Uses. Risperpine at low doses, in combination with diuretics, is effective in the treatment of hypertension, especially in the elderly. Several weeks are necessary to achieve maximum effect. In elderly patients with isolated systolic hypertension, risperpine (at 0.05 mg/d) was used as an alternative to atenolol together with a diuretic (Perry et al., 2000; SHEP Cooperative Research Group, 1991). However, with the availability of newer drugs that have proven life-prolonging effects and are well tolerated, the use of risperpine has largely diminished, and it is no longer recommended for the treatment of hypertension (Mancia et al., 2013).

Inhibitors of the Renin-Angiotensin System

Angiotensin II is an important regulator of cardiovascular function (see Chapter 26). The capacity to reduce the effects of AngII with pharmacological agents has been an important advance in the treatment of hypertension and its sequelae. Chapter 26 presents the basic physiology of the RAS and the pharmacology of inhibitors of the RAS. Table 26–2 summarizes the effects of a variety of antihypertensive agents on components of the RAS and warrants careful study.

Angiotensin-Converting Enzyme Inhibitors

The ability to reduce levels of AngII with orally effective ACE inhibitors represents an important advance in the treatment of hypertension. Captopril was the first such agent to be developed for the treatment of hypertension. Since then, enalapril, lisinopril, quinapril, ramipril, benazepril, moexipril, fosinopril, trandolapril, and perindopril have become available. These drugs are useful for the treatment of hypertension because of their efficacy and a favorable adverse effect profile that enhances patient adherence. Chapter 26 presents the pharmacology of ACE inhibitors in detail.

The ACE inhibitors appear to confer a special advantage in the treatment of patients with diabetes, slowing the development and progression of diabetic glomerulosclerosis. They also are effective in slowing the progression of other forms of chronic renal disease, such as glomerulosclerosis, which coexists with hypertension in many patients. An ACE inhibitor is the preferred initial agent in these patients. Patients with hypertension and ischemic heart disease are candidates for treatment with ACE inhibitors. Administration of ACE inhibitors in the immediate post-MI period has been shown to improve ventricular function and reduce morbidity and mortality (see Chapter 27).

The endocrine consequences of inhibiting the biosynthesis of AngII are of importance in a number of facets of hypertension treatment. Because ACE inhibitors blunt the rise in aldosterone concentrations in response to Na+ loss, the normal role of aldosterone to oppose diuretic-induced natriuresis is diminished. Consequently, ACE inhibitors tend to enhance the efficacy of diuretic drugs. This means that very small doses of diuretics may substantially improve the antihypertensive efficacy of ACE inhibitors; conversely, the use of high doses of diuretics together with ACE inhibitors may lead to excessive reduction in blood pressure and to Na+ loss in some patients.

Attenuation of aldosterone production by ACE inhibitors also influences K+ homeostasis; there is a small and clinically unimportant rise in serum K+ when these agents are used alone in patients with normal renal function. However, substantial retention of K+ can occur in some patients with renal insufficiency. Furthermore, the potential for developing hyperkalemia should be considered when ACE inhibitors are used with other drugs that can cause K+ retention, including the K+-sparing
modulation of pulmonary, renal, and cardiovascular function. Cough is a common (~5%) adverse effect and a reason to switch to AT_{1} receptor blockers. Angioedema is a rare but serious and potentially fatal adverse effect of the ACE inhibitors. Patients starting treatment with these drugs should be explicitly warned to discontinue their use with the advent of any signs of angioedema. Due to the risk of severe fetal adverse effects, ACE inhibitors are contraindicated during pregnancy; a fact that should be communicated to women of childbearing age.

In most patients, there is little or no appreciable change in glomerular filtration rate following the administration of ACE inhibitors. However, in renovascular hypertension, the glomerular filtration rate is generally maintained as the result of increased resistance in the postglomerular arteriole caused by AngII. Accordingly, in patients with bilateral renal artery stenosis or stenosis in a sole kidney, the administration of an ACE inhibitor will reduce the filtration fraction and cause a substantial reduction in glomerular filtration rate. In some patients with preexisting renal disease, the glomerular filtration may decrease with an ACE inhibitor. Thus, it should be kept in mind that ACE inhibitors, while inhibiting the progression of chronic kidney disease, carry a risk of irreversible drug-induced impairment of glomerular filtration. Serum creatinine levels and K+ should therefore be monitored in the first weeks after establishing therapy. Increases of serum creatinine of greater than 20% predict the presence of renal artery stenosis (van de Ven et al., 1998) and are a reason to discontinue the treatment with ACE inhibitors.

The ACE inhibitors lower the blood pressure to some extent in most patients with hypertension. Following the initial dose of an ACE inhibitor, there may be a considerable fall in blood pressure in some patients; this response to the initial dose is a function of plasma renin activity prior to treatment. The potential for a large initial drop in blood pressure is the reason for using a low dose to initiate therapy, especially in patients who may have a very active RAS supporting blood pressure, such as patients with diuretic-induced volume contraction or congestive heart failure. It should also be realized that, generally, no reason exists for normalizing blood pressure in a few days in patients with a lifelong disease. Attempts to do so increase the frequency of side effects and decrease compliance. With continuing treatment, there usually is a progressive fall in blood pressure that in most patients does not reach a maximum for several weeks. The blood pressure seen during chronic treatment is not strongly correlated with the pretreatment plasma renin activity: Young and middle-aged Caucasian patients have a higher probability of responding to ACE inhibitors; elderly African American patients as a group are more resistant to the hypotensive effect of these drugs. While most ACE inhibitors are approved for once-daily dosing for hypertension, a significant fraction of patients has a response that lasts less than 24 h and may require twice-daily dosing for adequate control of blood pressure (e.g., enalapril, ramipril). Captopril, with its very short duration of action, is not a good choice in the treatment of hypertension.

AT_{1} Receptor Blockers

The importance of AngII in regulating cardiovascular function has led to the development of nonpeptide antagonists of the AT_{1} subtype of AngII receptor. Losartan, candesartan, irbesartan, valsartan, telmisartan, olmesartan, and eprosartan have been approved for the treatment of hypertension. The pharmacology of AT_{1} receptor blockers is presented in detail in Chapter 26. By antagonizing the effects of AngII, these agents relax smooth muscle and thereby promote vasodilation, increase renal salt and water excretion, reduce plasma volume, and decrease cellular hypertrophy. Given the central role of AT_{1} receptors for the action of AngII, it is not surprising that AT_{1} receptor blockers have the same pharmacological profile as ACE inhibitors with one notable exception. AT_{1} receptor blockers do not inhibit the ACE-mediated degradation of bradykinin and substance P and thereby cause no cough.

Initial hopes for superiority of AT_{1} receptor blockers over ACE inhibitors have not been fulfilled. They were based on the idea that the AT_{1} subtype elicits beneficial effects of AngII (e.g., antigrowth and antiproliferative responses). Because the AT_{1} receptor mediates feedback inhibition of renin release, renin and AngII concentrations are increased during AT_{1} receptor antagonism, leading to increased stimulation of uninhibited AT_{1} receptors. Despite considerable interest, not much evidence supports any extra benefit from AT_{1} blockade versus ACE inhibition, and attempts to show greater reductions in cardiovascular events by AT_{1} receptor blockers or by the combination of an AT_{1} receptor blocker plus an ACE inhibitor over ACE inhibitor alone failed. ON-TARGET, one of the largest studies to date in patients with high vascular risk (70% hypertension) showed that telmisartan caused less cough and angioedema than ramipril (1.1% vs. 4.2%, and 0.1% vs. 0.3%) but had identical efficacy. The combination, although not more efficacious, was associated with greater worsening of renal function (13.5% vs. 10.2%), hypotension, and syncope (Yusuf et al., 2008).

Therapeutic Uses

The AT_{1} receptor blockers have a sufficient 24-h effect at once-daily dosing (except losartan). The full effect of AT_{1} receptor blockers on blood pressure typically is not observed until about 4 weeks after the initiation of therapy. If blood pressure is not controlled by an AT_{1} receptor blocker alone, a second drug acting by a different mechanism (e.g., a diuretic or Ca^{2+} channel blocker) may be added. The combination of an ACE inhibitor and an AT_{1} receptor blocker is not recommended for the treatment of hypertension.

Adverse Effects and Precautions

Adverse effects of ACE inhibitors that result from inhibiting AngII-related functions (see previous discussion and Chapter 26) also occur with AT_{1} receptor blockers. These include hypotension, hyperkalemia, and reduced renal function, including that associated with bilateral renal artery stenosis and stenosis in the artery of a solitary kidney. Hypotension is most likely to occur in patients in whom the blood pressure is highly dependent on AngII, including those with volume depletion (e.g., with diuretics), renovascular hypertension, cardiac failure, and cirrhosis; in such patients, initiation of treatment with low doses and attention to blood volume are essential. Hyperkalemia may occur in conjunction with other factors that alter K+ homeostasis, such as renal insufficiency, ingestion of excess K+, and the use of drugs that promote K+ retention. Cough and angioedema occur rarely. ACE inhibitors and AT_{1} receptor blockers should not be administered during pregnancy and should be discontinued as soon as pregnancy is detected.

Direct Renin Inhibitors

Aliskiren, the first orally effective direct renin inhibitor is FDA-approved for the treatment of hypertension. The detailed pharmacology of aliskiren is covered in Chapter 26. Aliskiren is an effective antihypertensive drug but has not been studied sufficiently in monotherapy of hypertension. A large study comparing a placebo or aliskiren added to a background of an ARB or an ACE inhibitor was stopped prematurely for a trend toward increased cardiovascular events in the aliskiren treatment group (Mcmurray et al., 2012). The combination also induced more renal worsening, hypotension, and hyperkalemia. This mirrors previous studies with ARB/ACE inhibitor combinations and indicates that complete blockade of the RAS system achieves more harm than benefit.

Pharmacology

The initial renin inhibitors were peptide analogues of sequences either in renin itself or included the renin cleavage site in angiotensinogen. While effective in inhibiting renin and lowering blood pressure, these peptide analogues were effective only parenterally. However, aliskiren is effective following oral administration; it directly and competitively inhibits the catalytic activity of renin, leading to diminished production of Angl, AngII, and aldosterone—with a resulting fall in blood pressure. Aliskiren along with ACE inhibitors and AT_{1} receptor blockers lead to an adaptive increase in the plasma concentrations of renin; however, because aliskiren inhibits renin activity, plasma renin activity does not increase as occurs with these other classes of drugs (Table 26–2). Nevertheless, the
intracellular storage sites, opening of high-conductance Ca\(^{2+}\)-activated K\(^{+}\) channels. The decrease in blood pressure after administration of hydralazine is associated with a selective decrease in vascular resistance in the coronary tissues. The decrease in blood pressure following oral administration of hydralazine is not due to causative factors such as tachycardia and hyperkalemia. With a better understanding of the compensatory cardiovascular responses that accompany use of arteriolar vasodilators, hydralazine was combined with sympathetic agents and diuretics with greater therapeutic success. Nonetheless, its role in the treatment of hypertension has markedly diminished with the introduction of new classes of antihypertensive agents.

Vasodilators

Hydralazine

Hydralazine (1-hydrazinophthalazine) was one of the first orally active antihypertensive drugs to be marketed in the U.S.; however, the drug initially was used infrequently because of tachycardia and hypotension. With a better understanding of the compensatory cardiovascular responses that accompany use of arteriolar vasodilators, hydralazine was combined with sympathetic agents and diuretics with greater therapeutic success. Nonetheless, its role in the treatment of hypertension has markedly diminished with the introduction of new classes of antihypertensive agents.

Mechanism of Action

Hydralazine directly relaxes arteriolar smooth muscle with little effect on venous smooth muscle. The molecular mechanisms mediating this action are not clear but may ultimately involve a reduction in intracellular Ca\(^{2+}\) concentrations. While a variety of changes in cellular signaling pathways are influenced by hydralazine, precise molecular targets that explain its capacity to dilate arteries remain uncertain. Potential mechanisms include inhibition of inositol trisphosphate–induced release of Ca\(^{2+}\) from intracellular storage sites, opening of high-conductance Ca\(^{2+}\)-activated K\(^{+}\) channels in smooth muscle cells, and activation of an arachidonic acid, COX, and prostacyclin pathway that would explain sensitivity to NSAIDs (Maille et al., 2016).

Hydralazine-induced vasodilation is associated with powerful stimulation of the sympathetic nervous system, likely due to baroreceptor-mediated reflexes, resulting in increased heart rate and contractility, increased plasma renin activity, and fluid retention. These effects tend to counteract the antihypertensive effect of hydralazine.

Pharmacological Effects

Most of the effects of hydralazine are confined to the cardiovascular system. The decrease in blood pressure after administration of hydralazine is associated with a selective decrease in vascular resistance in the coronary, cerebral, and renal circulations, with a smaller effect in skin and muscle. Because of preferential dilatation of arterioles over veins, postural hypotension is not a common problem; hydralazine lowers blood pressure similarly in the supine and upright positions.

ADME

Following oral administration, hydralazine is well absorbed via the GI tract. Hydralazine is N-acetylated in the bowel and the liver, contributing to the drug’s low bioavailability (16% in fast acetylators and 35% in slow acetylators). The rate of acetylation is genetically determined; about half of the U.S. population acetylates rapidly, and half does so slowly. The acetylated compound is inactive; thus, the dose necessary to produce a systemic effect is larger in fast acetylators. Because the systemic clearance exceeds hepatic blood flow, extrahepatic metabolism must occur. Indeed, hydralazine rapidly combines with circulating a-keto acids to form hydrazones, and the major metabolite recovered from the plasma is hydralazine pyruvic acid hydrazone. This metabolite has a longer \( t_{1/2} \) than hydralazine but appears to be relatively inactive. Although the rate of acetylation is an important determinant of the bioavailability of hydralazine, it does not play a role in the systemic elimination of the drug, probably because hepatic clearance is so high that systemic elimination is principally a function of hepatic blood flow. The peak concentration of hydralazine in plasma and the peak hypotensive effect of the drug occur within 30–120 min of ingestion. Although its \( t_{1/2} \) in plasma is about 1 h, the hypotensive effect of hydralazine can last as long as 12 h. There is no clear explanation for this discrepancy.

Therapeutic Uses

Hydralazine is no longer a first-line drug in the treatment of hypertension on account of its relatively unfavorable adverse-effect profile. The drug has a role as a combination pill containing isosorbide dinitrate (BiDil) in the treatment of heart failure (see Chapter 29). Hydralazine may have utility in the treatment of some patients with severe hypertension, can be part of evidence-based therapy in patients with congestive heart failure (in combination with nitrates for patients who cannot tolerate ACE inhibitors or AT\(_{1}\) receptor blockers), and may be useful in the treatment of hypertensive emergencies, especially preeclampsia, in pregnant women. Hydralazine should be used with great caution in elderly patients and in hypertensive patients with CAD because of the possibility of precipitating myocardial ischemia due to reflex tachycardia. The usual oral dosage of hydralazine is 25–100 mg twice daily. Off-label twice-daily administration is as effective as administration four times a day for control of blood pressure, regardless of acylator phenotype. The maximum recommended dose of hydralazine is 200 mg/d to minimize the risk of drug-induced lupus syndrome.

Toxicity and Precautions

Two types of adverse effects occur after the use of hydralazine. The first, which are extensions of the pharmacological effects of the drug, include headache, nausea, flushing, hypotension, palpitations, tachycardia, dizziness, and angina pectoris. Myocardial ischemia can occur on account of increased O\(_{2}\) demand induced by the baroreceptor reflex–induced stimulation of the sympathetic nervous system. Following parenteral administration to patients with CAD, the myocardial ischemia may be sufficiently severe and protracted to cause frank MI. For this reason, parenteral administration of hydralazine is not advisable in hypertensive patients with CAD, hypertensive patients with multiple cardiovascular risk factors, or older patients. In addition, if the drug is used alone, there may be salt retention with development of high-output congestive heart failure. When combined with a β blocker and a diuretic, hydralazine is better tolerated, although adverse effects such as headache are still commonly described and may necessitate discontinuation of the drug.

The second type of adverse effect is caused by immunological reactions, of which the drug-induced lupus syndrome is the most common. Administration of hydralazine also can result in an illness that resembles serum sickness, hemolytic anemia, vasculitis, and rapidly progressive glomerulonephritis. The mechanism of these autoimmune reactions is unknown, although it may involve the drug’s capacity to inhibit DNA methylation (Arce et al., 2006). The drug-induced lupus syndrome usually occurs after at least 6 months of continuous treatment with hydralazine, and its incidence is related to dose, gender, acetylator phenotype, and race. In one study, after 3 years of treatment with hydralazine, drug-induced lupus occurred in 10% of patients who received 200 mg daily, 5% who received 100 mg daily, and none who received 50 mg daily (Cameron and Ramsay, 1984). The incidence is four times higher in women than in men, and the syndrome is seen more commonly in Caucasians than in African Americans. The rate of conversion to a positive antinuclear antibody
test is faster in slow acetylators than in rapid acetylators, suggesting that the native drug or a nonacetylated metabolite is responsible. However, the majority of patients with positive antinuclear antibody tests do not develop the drug-induced lupus syndrome, and hydralazine need not be discontinued unless clinical features (arthritis, arthralgia, and fever) of the syndrome appear. Discontinuation of the drug is all that is necessary for most patients with the hydralazine-induced lupus syndrome, but symptoms may persist in a few patients, and administration of corticosteroids may be necessary.

Hydralazine also can produce a pyridoxine-responsive polyneuropathy. The mechanism appears to be related to the ability of hydralazine to combine with pyridoxine to form a hydrazone. This side effect is unusual with doses of 200 mg/d or less.

K\textsubscript{ATP} Channel Openers: Minoxidil

The discovery in 1965 of the hypotensive action of minoxidil was a significant advance in the treatment of hypertension; the drug has proven to be efficacious in patients with the most severe and drug-resistant forms of hypertension.

Locus and Mechanism of Action

Minoxidil is not active in vitro but must be metabolized by hepatic sulfotransferase to the active molecule, minoxidil N-O sulfate; the formation of this active metabolite is a minor pathway in the metabolic disposition of minoxidil. Minoxidil sulfate relaxes vascular smooth muscle in isolated systems where the parent drug is inactive. Minoxidil sulfate activates the ATP-modulated K\textsuperscript{+} channel permitting K\textsuperscript{+} efflux, and causes hyperpolarization and relaxation of smooth muscle.

Pharmacological Effects

Minoxidil produces arteriolar vasodilation with essentially no effect on the capacitance vessels; the drug resembles hydralazine and diazoxide in this regard. Minoxidil increases blood flow to skin, skeletal muscle, the GI tract, and the heart more than to the CNS. The disproportionate increase in blood flow to the heart may have a metabolic basis in that administration of minoxidil is associated with a reflex increase in myocardial contractility and in cardiac output. The cardiac output can increase markedly, as much as 3- to 4-fold. The principal determinant of the elevation in cardiac output is the action of minoxidil on peripheral vascular resistance to enhance venous return to the heart; by inference from studies with other drugs, the increased venous return probably results from enhancement of flow in the regional vascular beds, with a fast time constant for venous return to the heart (Ogivie, 1985). The adrenergically mediated increase in myocardial contractility contributes to the increased cardiac output but is not the predominant causal factor.

The effects of minoxidil on the kidney are complex. Minoxidil is a renal artery vasodilator, but systemic hypotension produced by the drug occasionally can decrease renal blood flow. Renal function usually improves in patients who take minoxidil for the treatment of hypertension, especially if renal dysfunction is secondary to hypertension. Minoxidil is a potent stimulator of renin secretion. This effect is mediated by a combination of renal sympathetic stimulation and activation of the intrinsic renal mechanisms for regulation of renin release.

Discovery of K\textsubscript{ATP} channels in a variety of cell types and in mitochondria is prompting consideration of K\textsubscript{ATP} channel modulators as therapeutic agents in many cardiovascular diseases (Pollesello and Mebazaa, 2004). Minoxidil, similar to other K\textsubscript{ATP} channel openers such as diazoxide, pinacidil, and nicorandil, may have protective effects on the heart during ischemia/reperfusion (Sato et al., 2004). It also promotes the synthesis of vascular elastin in rats (Slove et al., 2013), a potentially interesting therapeutic effect.

ADME

Minoxidil is well absorbed from the GI tract. Although peak concentrations of minoxidil in blood occur 1 h after oral administration, the maximal hypotensive effect of the drug occurs later, possibly because formation of the active metabolite is delayed.

The bulk of the absorbed drug is eliminated as a glucuronide; about 20% is excreted unchanged in the urine. The extent of biotransformation of minoxidil to its active metabolite, minoxidil N-O sulfate, has not been evaluated in humans. Minoxidil has a plasma t\textsubscript{1/2} of 3–4 h, but its duration of action is 24 h and occasionally even longer. It has been proposed that persistence of minoxidil in vascular smooth muscle is responsible for this discrepancy, but without knowledge of the pharmacokinetic properties of the active metabolite, an explanation for the prolonged duration of action cannot be given.

Therapeutic Uses

Systemic minoxidil is best reserved for the treatment of severe hypertension that responds poorly to other antihypertensive medications, especially in male patients with renal insufficiency. Minoxidil has been used successfully in the treatment of hypertension in both adults and children. Minoxidil should never be used alone; it must be given concomitantly with a diuretic to avoid fluid retention, with a sympatholytic drug (e.g., β blocker) to control reflex cardiovascular effects and an inhibitor of the RAS to prevent remodeling effects on the heart. The drug usually is administered either once or twice a day, but some patients may require more frequent dosing for adequate control of blood pressure. The initial daily dose of minoxidil may be as little as 1.25 mg, which can be increased gradually to 40 mg in one or two daily doses.

Adverse Effects and Precautions

The adverse effects of minoxidil, which can be severe, fall into three major categories: fluid and salt retention, cardiovascular effects, and hypotension. Retention of salt and water results from increased proximal renal tubular reabsorption, which is secondary to reduced renal perfusion pressure and to reflex stimulation of renal tubular afferent receptors. Similar antinatriuretic effects can be observed with the other arteriolar dilators (e.g., diazoxide and hydralazine). Although administration of minoxidil causes increased secretion of renin and aldosterone, this is not an important mechanism for retention of salt and water in this case. Fluid retention usually can be controlled by the administration of a diuretic. However, thiazides may not be sufficiently efficacious, and it may be necessary to use a loop diuretic, especially if the patient has any degree of renal dysfunction.

The cardiac consequences of the baroreceptor-mediated activation of the sympathetic nervous system during minoxidil therapy are similar to those seen with hydralazine; there is an increase in heart rate, myocardial contractility, and myocardial O\textsubscript{2} consumption. Thus, myocardial ischemia can be induced by minoxidil in patients with CAD. The cardiac sympathicotropic responses are attenuated by concurrent administration of a β blocker. The adrenergically induced increase in renin secretion also can be ameliorated by a β blocker or an ACE inhibitor, with enhancement of blood pressure control.

The increased cardiac output evoked by minoxidil has particularly adverse consequences in those hypertensive patients who have left ventricular hypertrophy and diastolic dysfunction. Such poorly compliant ventricles respond suboptimally to increased volume loads, with a resulting increase in left ventricular filling pressure. This probably is a major contributor to the increased pulmonary artery pressure seen with minoxidil (and hydralazine) therapy in hypertensive patients and is compounded by the retention of salt and water caused by minoxidil. Cardiac failure can result from minoxidil therapy in such patients; the potential for this complication can be reduced but not prevented by effective diuretic therapy.

Pericardial effusion is an uncommon but serious complication of minoxidil. Mild and asymptomatic pericardial effusion is not an indication for discontinuing minoxidil, but the situation should be monitored closely to avoid progression to tamponade. Effusions usually clear when the drug is discontinued but can recur if treatment with minoxidil is resumed.

Flattened and inverted T waves frequently are observed in the electrocardiogram following the initiation of minoxidil treatment. These are not ischemic in origin and are seen with other drugs that activate K\textsuperscript{+} channels. In model systems, pinacidil is associated with a lowered ventricular fibrillation threshold and increased spontaneous ventricular fibrillation in the ischemic canine heart, and minoxidil causes cardiac arrhythmias...
in the rabbit; whether such findings translate to events in humans is unknown.

Excess hair growth occurs in patients who receive minoxidil for an extended period and is probably a consequence of K^+ channel activation. Growth of hair occurs on the face, back, arms, and legs and is particularly offensive to women. Frequent shaving or depilatory agents can be used to manage this problem. Topical minoxidil is marketed over the counter for the treatment of male pattern baldness and hair thinning and loss on the top of the head in women. The topical use of minoxidil also can cause measurable cardiovascular effects in some individuals.

Other side effects of the drug are rare and include rashes, Stevens-Johnson syndrome, glucose intolerance, serosanguineous bullae, formation of antinuclear antibodies, and thrombocytopenia.

**Sodium Nitroprusside**

Although sodium nitroprusside has been known since 1850 and its hypotensive effect in humans was described in 1929, its safety and usefulness for the short-term control of severe hypertension were not demonstrated until the mid-1950s. Several investigators subsequently demonstrated that sodium nitroprusside also was effective in improving cardiac function in patients with left ventricular failure (see Chapter 29).

**Mechanism of Action**

Nitroprusside is a nitrovasodilator that acts by releasing NO. NO activates the guanylyl cyclase–cyclic guanosine monophosphate–protein kinase G pathway, leading to vasodilatation, mimicking the production of NO by vascular endothelial cells, which is impaired in many hypertensive patients. The mechanism of release of NO from nitroprusside is not clear and likely involves both enzymatic and nonenzymatic pathways. Tolerance develops to nitroglycerin but not to nitroprusside. The pharmacology of the organic nitrates, including nitroglycerin, is presented in Chapter 27.

**Pharmacological Effects**

Nitroprusside dilates both arterioles and venules, and the hemodynamic response to its administration results from a combination of venous pooling and reduced arterial impedance. In subjects with normal left ventricular function, venous pooling affects cardiac output more than does the reduction of afterload; cardiac output tends to fall. In contrast, in patients with severely impaired left ventricular function and diastolic ventricular distention, the reduction of arterial impedance is the predominant effect, leading to a rise in cardiac output (see Chapter 29).

Sodium nitroprusside is a nonselective vasodilator, and regional distribution of blood flow is little affected by the drug. In general, renal blood flow and glomerular filtration are maintained, and plasma renin activity is increased. Unlike minoxidil, hydralazine, diazoxide, and other arteriolar vasodilators, sodium nitroprusside usually causes only a modest increase in heart rate and an overall reduction in myocardial O_2_ demand.

**ADME**

Sodium nitroprusside is an unstable molecule that decomposes under strongly alkaline conditions or when exposed to light. The drug must be protected from light and given by continuous intravenous infusion to be effective. Its onset of action is within 30 sec; the peak hypotensive effect occurs within 2 min, and when the infusion of the drug is stopped, the effect disappears within 3 min.

Sodium nitroprusside is available in vials that contain 50 mg. The contents of the vial should be dissolved in 2–3 mL of 5% dextrose in water. Because the compound decomposes in light, only fresh solutions should be used, and the bottle should be covered with an opaque wrapping. The drug must be administered as a controlled continuous infusion, and the patient must be closely observed. The majority of hypertensive patients respond to an infusion of 0.25–1.5 μg/kg/min. Higher infusion rates are necessary to produce controlled hypotension in normotensive patients under surgical anesthesia. Patients who are receiving other antihypertensive medications usually require less nitroprusside to lower blood pressure. If infusion rates of 10 μg/kg/min do not produce adequate reduction of blood pressure within 10 min, the rate of administration of nitroprusside should be reduced to minimize potential toxicity.

The metabolism of nitroprusside by smooth muscle is initiated by its reduction, which is followed by the release of cyanide and then NO. Cyanide is further metabolized by hepatic rhodanase to form thiocyanate, which is eliminated almost entirely in the urine. The mean elimination half-time t_1/2_ for thiocyanate is 3 days in patients with normal renal function and much longer in patients with renal insufficiency.

**Therapeutic Uses**

Sodium nitroprusside is used primarily to treat hypertensive emergencies but also can be used in situations when short-term reduction of cardiac preload or afterload is desired. Nitroprusside has been used to lower blood pressure during acute aortic dissection; to improve cardiac output in congestive heart failure, especially in hypertensive patients with pulmonary edema that does not respond to other treatment (see Chapter 29); and to decrease myocardial O_2_ demand after acute MI. In addition, nitroprusside is used to induce controlled hypotension during anesthesia to reduce bleeding in surgical procedures. In the treatment of acute aortic dissection, it is important to administer a β blocker with nitroprusside because reduction of blood pressure with nitroprusside alone can increase the rate of rise in pressure in the aorta as a result of increased myocardial contractility, thereby enhancing propagation of the dissection.

**Toxicity and Precautions**

The short-term adverse effects of nitroprusside are due to excessive vasodilation, with hypotension and its consequences. Close monitoring of blood pressure and the use of a continuous variable-rate infusion pump will prevent an excessive hemodynamic response to the drug in the majority of cases.

Less commonly, toxicity may result from conversion of nitroprusside to cyanide and thiocyanate. Toxic accumulation of cyanide leading to severe lactic acidosis usually occurs when sodium nitroprusside is infused at a rate greater than 5 μg/kg/min but also can occur in some patients receiving doses on the order of 2 μg/kg/min for a prolonged period. The limiting factor in the metabolism of cyanide appears to be the availability of sulfur-containing substrates in the body (i.e., mainly thiosulfate). The concomitant administration of sodium thiosulfate can prevent accumulation of cyanide in patients who are receiving higher-than-usual doses of sodium nitroprusside; the efficacy of the drug is unchanged. The risk of thiocyanate toxicity increases when sodium nitroprusside is infused for more than 24–48 h, especially if renal function is impaired. Signs and symptoms of thiocyanate toxicity include anorexia, nausea, fatigue, disorientation, and toxic psychosis. The plasma concentration of thiocyanate should be monitored during prolonged infusions of nitroprusside and should not be allowed to exceed 0.1 mg/mL. Rarely, excessive concentrations of thiocyanate may cause hypothyroidism by inhibiting iodine uptake by the thyroid gland. In patients with renal failure, thiocyanate can be removed readily by hemodialysis.

Nitroprusside can worsen arterial hypoxemia in patients with chronic obstructive pulmonary disease because the drug interferes with hypoxic pulmonary vasoconstriction and therefore promotes mismatching of ventilation with perfusion.

**Diazoxide**

Diazoxide was used in the treatment of hypertensive emergencies but fell out of favor at least in part due to the risk of marked falls in blood pressure when large bolus doses of the drug were used. Other drugs are now preferred for parenteral administration in the control of hypertension. Diazoxide also is administered orally to treat patients with various forms of hypoglycemia (see Chapter 47).
Nonpharmacological Therapy of Hypertension

Nonpharmacological approaches to the treatment of hypertension may suffice in patients with modestly elevated blood pressure. Such approaches also can augment the effects of antihypertensive drugs in patients with more marked initial elevations in blood pressure. The indications and efficacy of various lifestyle modifications in hypertension were reviewed in recent guidelines (James et al., 2014; Mancia et al., 2013).

- Reduction in body weight for people who are modestly overweight or frankly obese may be useful (Goodpaster et al., 2010).
- Restricting sodium consumption lowers blood pressure in some patients.
- Restriction of ethanol intake to modest levels (daily consumption < 20 g in women, < 40 g in men) may lower blood pressure.
- Increased physical activity improves control of hypertension.
- Renal denervation may be effective in patients with well-defined resistant hypertension (Azizi et al., 2015).
- Bariatric surgery in grossly overweight individuals may normalize blood pressure and increase life expectancy (Sjostrom et al., 2007).

Selection of Antihypertensive Drugs in Individual Patients

Choice of antihypertensive drugs for individual patients may be complex; there are many sources of influence that modify therapeutic decisions. While results derived from randomized, controlled clinical trials are the optimal foundation for rational therapeutics, sorting through the multiplicity of those results and addressing how to apply them to an individual patient can be vexing. While therapeutic guidelines can be useful in reaching appropriate therapeutic decisions, it often is difficult for clinicians to apply guidelines at the point of care, and guidelines often do not provide enough information about recommended drugs. In addition, intense marketing of specific drugs to both clinicians and patients may confound optimal decision-making. Moreover, persuading patients to continue taking drugs that may be expensive for an asymptomatic disease is a challenge. Clinicians may be reluctant to prescribe and patients reluctant to consume the number of drugs that may be necessary to adequately control blood pressure. For these and other reasons, perhaps one-half of patients being treated for hypertension have not achieved therapeutic goals in blood pressure lowering.

Choice of an antihypertensive drug should be driven by the likely benefit in an individual patient, taking into account concomitant diseases such as diabetes mellitus, problematic adverse effects of specific drugs, and cost. The last factor is losing relevance as the most important antihypertensive drug classes (diuretics, Ca^2+ channel blockers, ACE inhibitors/AT, receptor blockers, β blockers) are out of patent protection and available as generics.

After a long debate about blood pressure-independent effects of certain antihypertensive drug classes, there is a consensus that blood pressure lowering per se is the most important goal of antihypertensive treatment. This conclusion is based on a number of large comparative prospective trials that, overall, did not show major differences in outcome depending on drug class (reviewed by Mancia et al., 2013). The JNC8 guidelines formulated a preference for an initial therapy with thiazide diuretics, Ca^2+ channel blockers, and ACE inhibitor/ARB in the general non-black population (including diabetics) and a preference for thiazides and Ca^2+ channel blockers in black patients (James et al., 2014). The ESC guidelines state that “although meta-analyses occasionally appear, claiming superiority of one class of agents over another for some outcomes, this largely depends on the selection bias of trials, and the largest meta-analyses available do not show clinically relevant differences between drug classes.” They conclude “that diuretics (including thiazides, chlorothalidone and indapamide), β blockers, calcium channel blockers, ACE inhibitors and AT, receptor blockers are all suitable for the initiation and maintenance of antihypertensive treatment, either as monotherapy or in some combinations” (Mancia et al., 2013). Major guideline recommendations around the world have been recently compared (Kjeldsen et al., 2014) and are the basis of recommendations for a compilation of drug choices in Table 28–4.

A number of pharmacological principles should be considered for optimizing the antihypertensive drug regimen.

1. **Pharmacokinetics:** Hypertension is a chronic, often lifelong disease without major symptoms but with serious complications, making compliance to antihypertensive drugs a factor of utmost prognostic importance. Antihypertensives should be chosen that exhibit relative even plasma concentrations at once-daily dosing, achieving sufficient 24-h control of blood pressure and trough-peak effect ratios greater than 50%. The longer the half-life, the less the variation of plasma concentrations (e.g., chlorothalidone vs. hydrochlorothiazide). Drugs with stable pharmacokinetics, that is, low drug interaction potential and no pharmacogenetic influence, are preferred (e.g., bisoprolol vs. metoprolol).

2. **Drug combinations:** Two-thirds of patients with hypertension require two or more antihypertensives for sufficient blood pressure control (<140/90 mmHg). It is therefore reasonable to start combining drugs at low-to-medium doses instead of increasing the dose of a single drug. Prescribing fixed drug combinations (e.g., a Ca^2+ channel blocker + ACE inhibitor or an ACE inhibitor + diuretic) improves compliance.

3. **Strength of scientific evidence:** Data from large prospective trials provide a high level of confidence for a beneficial risk-benefit ratio and are a reason to use one drug over another.

</table>

The drug choices depicted represent a combined view from nine guidelines that differ; thus, the table is, necessarily, a didactic simplification (for details, consult Kjeldsen et al., 2014).
4. **Pharmacodynamic considerations:** Although not formally tested in prospective trials, certain drug combinations make more sense than others. Thiazide diuretics increase the antihypertensive actions of all other classes, but their combination with RAS inhibitors makes particular sense as their K⁺-sparing effect and thus their main risk are reduced by members of this class.

5. **Adverse drug effects and contraindications:** The major classes of antihypertensives are generally well tolerated and, in placebo-controlled trials, showed rates of adverse effects in the range of placebo with some notable exceptions that need to be taken into consideration when choosing a specific drug for a specific patient (Table 28–5). The rate of adverse effects such as hypotension or bradycardia can be largely reduced by starting antihypertensives at low doses and employing a slow dose-escalation strategy.

6. **Compelling indications:** A number of compelling indications exist for specific antihypertensive agents on account of other serious, underlying cardiovascular disease (Table 28–4). These include heart failure, CAD, post-MI, chronic kidney disease, or diabetes. For example, a hypertensive patient with congestive heart failure ideally should be treated with a diuretic, β blocker, ACE inhibitor/AT₁ receptor blocker, and, in selected patients, spironolactone because of the benefit of these drugs in congestive heart failure, even in the absence of hypertension (see Chapter 29). Similarly, ACE inhibitors/AT₁ receptor blockers should be first-line drugs in the treatment of diabetics with hypertension in view of these drugs’ well-established benefits in diabetic nephropathy.

7. **Comorbidities:** Some patients have other diseases that could influence the choice of antihypertensive drugs. For example, a hypertensive patient with symptomatic benign prostatic hyperplasia might benefit from having an α₁ blocker as part of his therapeutic program because α₁ blockers are efficacious in both diseases. Similarly, a patient with recurrent migraine attacks might particularly benefit from use of a β blocker because a number of drugs in this class are efficacious in preventing migraine attacks. Women with a high risk of osteoporosis may benefit from the Ca²⁺-increasing effect of thiazide diuretics. On the other hand, in pregnant hypertensives, some drugs that are otherwise little used (e.g., methyldopa) may be preferred and popular drugs (e.g., ACE inhibitors) need to be avoided on account of concerns about safety.

8. **Second- and third-line hypertensives:** In the vast majority of cases, hypertension can well be controlled by antihypertensives of the five major classes with or without spironolactone at low doses. However, patients with chronic kidney disease often require the additional use of drugs such as hydralazine or minoxidil. The place of clonidine/moxonidine or α₁ blockers in the treatment of hypertension is not well defined.

---

**Acute Antihypertensive Treatment**

The considerations mentioned apply to patients with hypertension who need treatment to reduce long-term risk, not patients in immediately life-threatening settings due to hypertension. While there are limited

</tbody>
</table>

*Possible contraindications and precautions noted in column 3 are not formal contraindications, but rather patient characteristics that should be considered on an individual basis and that may mitigate against use of a class of drugs (e.g., metabolic syndrome and glucose intolerance for diuretics and β blockers). Similarly, some patients with chronic obstructive lung disease can be treated with β blockers without deterioration of lung function, whereas other patients may experience significant bronchoconstriction with β blockers.*
clinical trial data, clinical judgment favors rapidly lowering blood pressure in patients with life-threatening complications of hypertension, such as encephalopathy or pulmonary edema due to severe hypertension. However, rapid reduction in blood pressure has considerable risks for the patients; if blood pressure is decreased too quickly or extensively, cerebral blood flow may diminish due to adaptations in the cerebral circulation that protect the brain from the sequelae of very high blood pressures. The temptation to treat patients merely on the basis of increased blood pressure should be resisted. Appropriate therapeutic decisions need to encompass how well a patient’s major organs are reacting to blood pressure in emergencies (including need to encompass how well a patient’s major organs are reacting to blood pressure). To achieve cance of differing actions of many of these drugs in this setting is largely unknown (Perez et al., 2009).

### Resistant Hypertension

Some patients with hypertension fail to respond to recommended antihypertensive treatments. There are many potential explanations. To achieve stringent control of hypertension, many patients require two, three, or four appropriately selected drugs used at optimal doses. Exhibiting an abundance of caution and therapeutic inertia, clinicians may be reluctant to prescribe sufficient numbers of medications that exploit the drugs’ full dose-response curves; conversely, patients may not adhere to the recommended pharmacological regimen. Sometimes, multiple drugs in the same therapeutic class that act by the same mechanism are combined; that is generally not a rational approach. Excess salt intake and the tendency of some antihypertensive drugs, especially vasodilators, to promote salt retention may mitigate falls in blood pressure; consequently, inadequate diuretic treatment commonly is found in patients with resistant hypertension. A relevant fraction of patients with resistant hypertension has primary hyperaldosteronism and benefits from the addition of daily spironolactone at 25–50 mg (Williams et al., 2015). Patients may take prescription drugs, over-the-counter drugs, or herbal preparations that oppose the actions of antihypertensive drugs (e.g., NSAIDs, sympathomimetic decongestants, cyclosporine, erythropoietin, ephedra [also called ma huang], or licorice). Illicit drugs such as cocaine and amphetamines may raise blood pressure. The physician must inquire about a patient’s other medications and supplements and individualize the antihypertensive regimen.

**Acknowledgment:** Thomas Michel and Brian B. Hoffman contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.

Magee LA, et al. Do labelatol and methyldopa have different effects on pregnancy outcome? Analysis of data from the Control of Hypertension In Pregnancy Study (CHIPS) trial. BJOG, 2016, 123:1143–1151.

Heart failure is responsible for more than half a million deaths annually in the U.S. Its prevalence is increasing worldwide, likely due to improved survival of those who have had an acute myocardial infarction and an aging population. Median survival rates after the first hospitalization associated with heart failure are worse than those of most cancers, but associated with heart failure are worse than those of most cancers, but are improving over the past 30 years (1.3 to 2.3 years in men and 1.3 to 1.7 years in women) (Jhund et al., 2009). This positive trend was associated with a 2- to 3-fold higher prescription rate of ACEIs and ARBs, β receptor antagonists (β blockers), and MRAs, suggesting that improved drug therapy has contributed to enhanced survival of heart failure.

Pathophysiology of Heart Failure

Definitions
Heart failure is a state in which the heart is unable to pump blood at a rate commensurate with the requirements of the body's tissues or can do so only at elevated filling pressure. This leads to symptoms that define the heart failure syndrome clinically. Low output (forward failure) causes fatigue, dizziness, muscle weakness, and shortness of breath, which is aggravated by physical exercise. Increased filling pressure leads to congestion of the organs upstream of the heart (backward failure), clinically apparent as peripheral or pulmonary edema, maldigestion, and ascites.

Most patients with heart failure are diagnosed exclusively on the basis of symptoms; that is, their heart function has never been directly measured (e.g., by echocardiography). Under these circumstances, it is not possible to differentiate between HFpEF (or systolic heart failure) and HFrEF (or diastolic heart failure, see discussion that follows). Other diseases associated with similar symptoms can therefore be wrongly categorized as heart failure (e.g., chronic obstructive pulmonary disease).

Common Final Pathway of Multiple Cardiac Diseases
Heart failure is not a single disease entity but a clinical syndrome that represents the final pathway of multiple cardiac diseases. The most common reason for systolic heart failure today is ischemic heart disease causing either acute (myocardial infarction) or chronic loss of viable heart muscle mass. Other reasons include chronic arterial hypertension and valvular diseases (both are decreasing in incidence due to improved therapy), genetically determined primary heart muscle defects (cardiomyopathies), viral infections (cytomegalovirus and possibly parvovirus), and toxins. The last encompass excessive alcohol, cocaine, amphetamines, and cancer drugs such as doxorubicin or trastuzumab, the monoclonal antibody directed against the growth factor receptor Her-2/Erb-B2 (see Chapter 67).

Pathophysiological Mechanisms
The pathophysiology of systolic heart failure is relatively well understood. The mechanisms of HFpEF are much less clear, but surely differ and are discussed further in this chapter. The pathophysiology of heart failure is complex and involves four major interrelated systems (Figure 29–1):

- the heart itself
- the vasculature
- the kidney
- neurohumoral regulatory circuits

The Heart Itself: Cardiomyopathy of the Overload
Any overload of the myocardium—loss of relevant muscle mass, which overloads the remaining healthy myocardium; chronic hypertension; or valvular defects—will eventually lead to the organ's failure to produce sufficient cardiac output. This concept can be extended to the genetically determined cardiomyopathies in which essentially any defect in an organelle of cardiac myocytes can lead to primary myocyte contractile dysfunction and then, secondarily, to the picture commonly seen in the cardiomyopathy of the overload. Not surprisingly, the most common cardiomyopathies (HCM, DCM) are due to mutations in genes encoding proteins of the contractile machinery, the sarcomere, proteins anchoring the sarcomere to the plasma membrane, or proteins mediating and maintaining cell-cell contact.

The overload (or the primary contractile defect) leads to alterations of the heart that can partially compensate but that come at a price. Because cardiac myocytes essentially stop replicating in the early postnatal period,
Abbreviations

ACC: American College of Cardiology
ACE: angiotensin-converting enzyme
ACEI: angiotensin-converting enzyme inhibitor
ACH: acetylcholine
ADH: antidiuretic hormone (vasopressin)
ADR: adverse drug reaction
AF: atrial fibrillation
AHA: American Heart Association
AngII: angiotensin II
ANP: atrial natriuretic peptide
ARB: AT1 angiotensin receptor antagonist (blocker)
ARNI: angiotensin receptor/neprilysin inhibitor
AV: atrioventricular
AVP: arginine vasopressin
BB: β blocker
BNP: brain-type natriuretic peptide
CAD: coronary artery disease
CCB: calcium channel blocker
CG: cardiac glycoside
CHF: congestive heart failure
CM: cardiomyopathy
CNP: C-type natriuretic peptide
COX: cyclooxygenase
CPT1: Carnitine palmitoyltransferase 1
CRT: cardiac resynchronization therapy
CYP: cytochrome P450
DCM: dilated cardiomyopathy
DM: diabetes mellitus
EGG: electrocardiogram
EF: ejection fraction
EMA: European Medicines Agency
eNOS: endothelial nitric oxide synthase
EPI: epinephrine
ESC: European Society of Cardiology
ET: endothelin
FDA: Food and Drug Administration
GC: guanylyl cyclase
GDMT: guideline-directed medical therapy
GFR: glomerular filtration rate
Gi: gastrointestinal
GPCR: G protein–coupled receptor
GTN: glycerol trinitrate
HCM: hypertrophic cardiomyopathy
HCN: hyperpolarization-activated, cyclic nucleotide–gated cation channel
HF: heart failure
HFpEF: heart failure with preserved ejection fraction (diastolic heart failure)
HFrEF: heart failure with reduced ejection fraction (systolic heart failure)
HMG CoA: 3-hydroxy-3-methylglutaryl coenzyme A
HRQOL: health-related quality of life
HTN: hypertension
ICD: implantable cardioverter-defibrillator
ISDN: isosorbide 5′-dinitrate
ISMN: isosorbide 5′-mononitrate
LV: left ventricular
LVH: left ventricular hypertrophy
MCS: mechanical circulatory support
MI: myocardial infarction
MRA: mineralocorticoid receptor antagonist
NCX: Na+/Ca2+ exchanger
NE: norepinephrine
NO: nitric oxide
NSAID: nonsteroidal anti-inflammatory drug
NYHA: New York Heart Association
PD: pharmacodynamic
PDE: cyclic nucleotide phosphodiesterase
PKA: protein kinase A
PLB: phospholamban
PLM: phospholemman
RAAS: renin-angiotensin-aldosterone system
ROS: reactive oxygen species
RyR: ryanodine receptor
SERCA: sarco/endoplasmic reticulum Ca2+ ATPase
sGC: soluble guanylyl cyclase
SL: sarcolemma
SNS: sympathetic nervous system
SR: sarcoplasmic reticulum
TnC: troponin C
TNF: tumor necrosis factor
TnI: inhibitory subunit of troponin

The Vasculature

A critical parameter of cardiac function is the stiffness of the vasculature. It determines the resistance against which the heart has to expel the blood and increases with aging. Heart failure may be the consequence of premature aging of the vasculature (Strait and Lakatta, 2012). Aging-induced loss of elasticity of the great blood vessels reduces their compliance, that is, the elasticity that permits vessels to extend in systole and contract in diastole. Good compliance reduces peak systolic pressure and increases diastolic pressure, which favors perfusion in diastole. It is negatively correlated with pulse pressure, that is, the difference between systolic and diastolic blood pressure, which is low in children and high in the elderly. Arterial hypertension and diabetes mellitus are the major reasons for premature stiffening of blood vessels, which imposes increased afterload to the heart and contributes to heart failure. Theoretically, stiffening and loss of compliance could be directly tackled by drugs (see section Recent Developments; Novel Approaches).

Another critical aspect of vascular function is the ability to adapt the vessel diameter to hemodynamic and neurohumoral stimuli, a function
that is governed by cross talk between luminal endothelial and underlying smooth muscle cells (Chapter 28). The main signaling pathway involves receptors that increase intracellular Ca\(^{2+}\) levels in endothelial cells, which activates eNOS to produce NO. This gaseous transmitter diffuses into smooth muscle cells and activates sGC to produce cGMP, which causes relaxation of vascular smooth muscle. Heart failure is always accompanied by endothelial dysfunction, which is a disturbed balance between vasodilating NO and proconstrictor ROS. ROS, by inactivating the two critical enzymes eNOS and sGC and converting NO to peroxynitrite, a strong ROS, favor vasoconstriction. Several common cardiovascular drugs (ACEIs/ARBs, MRAs, statins) improve endothelial function by reducing ROS production. PDE5 inhibitors have similar consequences by inhibiting cGMP degradation in smooth muscle cells and thereby promoting relaxation.

**The Kidney**

The kidney regulates Na\(^+\) and H\(_2\)O excretion and thereby intravascular volume. Under normal conditions, autoregulatory and neurohumoral mechanisms ensure an adequate GFR and diuresis over a wide range of renal perfusion pressures. Prominent mechanisms with relevance for heart failure are (1) the AngII-mediated regulation of filtration rate by regulating the diameter of efferent glomerular arteriole; (2) the regulation of kidney perfusion by a balance between constrictor-promoting effects of AngII (via AT\(_1\) receptors) and vasopressin (AVP, via V\(_2\) receptors) and the vasodilating influence of prostaglandins (hence the deleterious effects of NSAIDs); (3) the aldosterone-mediated regulation of Na\(^+\) reabsorption in the distal tubule; and (4) AVP-regulated water transport in the collecting ducts (via V\(_2\) receptors). In heart failure, all mechanisms are dysregulated and constitute therapeutic targets of ACEIs/ARBs, MRAs, and diuretics. Newer agents, such as adenosine A\(_2\), receptor antagonists and AVP receptor antagonists, have failed to exert therapeutic benefit in clinical studies.

**Neurohumoral Regulation and HFrEF**

The decrease in cardiac output in heart failure leads to the activation of the SNS and the RAAS and increases in plasma levels of AVP and ET (Figure 29–1). This concerted response ensures the perfusion of centrally important organs such as the brain and the heart (at the expense of kidney, liver, and skeletal muscle perfusion) in situations of acute blood loss. These responses are components of the “fight-or-flight response” and provide useful short-term physiological responses to alarm and danger. Chronically, however, neurohumoral activation exerts deleterious effects that constitute a vicious cycle in heart failure. Vasoconstriction initially not only stabilizes blood pressure but also increases afterload, which is the resistance against which the heart works to expel blood (see Figures 29–4 and 27–1). Because of the decreased contractile reserve, the failing heart is particularly sensitive to increases in afterload (see Figure 29–4); such increases further decrease cardiac output. Decreased kidney perfusion and increased aldosterone production reduce diuresis and promote volume overload, which increases cardiac preload, dilation, and ventricular wall stress, a major determinant of cardiac O\(_2\) consumption. Tachycardic and positive inotropic actions of catecholamines not only acutely increase cardiac output but also promote arrhythmias and increase O\(_2\) consumption in a failing, energy-depleted heart. AngII, NE, and ET accelerate pathological cardiac remodeling (hypertrophy, fibrosis, and cell death). Aldosterone has prominent profibrotic actions. This spectrum of adverse consequences of chronic neurohumoral activation explains why inhibitors of these systems (ACEIs/ARBs, β blockers, and MRAs) exert long-term, life-prolonging effects in heart failure and are the cornerstones of current therapy.

Unexpectedly, ET and AVP receptor antagonists provide no beneficial effect in patients with heart failure, despite promising results in preclinical studies. Clinical trials suggested that neurohumoral activation in response to altered cardiac function may be sufficiently inhibited by the standard combination therapy, leaving no room for improvement from the addition of ET and AVP antagonists; however, recent data indicate that additional benefit may accrue via another therapeutic route: a drug combination called ARNIs. The FDA has approved a fixed-dose combination of the ARB valsartan with the neprilysin inhibitor sacubitril. Valsartan blocks AT\(_1\) receptors, reducing the deleterious effects of AngII.
Sacubitril inhibits the degradation of the natriuretic peptides ANP and BNP. The valsartan-sacubitril combination appears superior to the ACEI enalapril, reducing the rates of hospitalization and death from all cardiovascular causes in patients with HFpEF (Hubers and Brown, 2016).

This finding reflects the fact that neurohumoral activation in heart failure includes one system that exerts beneficial effects: the natriuretic peptides. Normally, ANP and BNP are expressed in the atria and released on increased preload (stretch). During heart failure, ANP and BNP are also produced by the ventricles, such that plasma levels are elevated. Indeed, BNP is used as a biomarker of heart failure. ANP and BNP stimulate the plasma membrane guanylyl cyclase. In the kidney, elevated cGMP has diuretic effects. Elevated cellular cGMP mediates vasodilation in the vasculature and, in the heart, antihypertrophic, antifibrotic, and compliance-increasing effects related to phosphorylation of titin. Enhancing these effects by inhibiting the degradation of ANP/BNP likely explains the clinical benefits of sacubitril-valsartan.

Heart Failure With Preserved Ejection Fraction

Systematic echocardiographic determination of left ventricular EF in hundreds of patients with heart failure revealed that about 50% had no reduction; that is, they exhibited EF values greater than 50%. Still, patients had typical heart failure symptoms, including acute decompensation with pulmonary edema and a survival prognosis not much better or even identical to patients with reduced EF (systolic heart failure or HFrEF). These data point to a different pathophysiology in which abnormalities of the diastolic and not the systolic component of cardiac function prevail. Due to difficulties in defining diastolic function by standard techniques, the term HFpEF has been introduced and applies to patients with typical heart failure symptoms and “normal” (>50%) or mildly reduced EF.

Even more than HFrEF, HFpEF is a multifactorial disease (Figure 29–2). HFpEF is typically associated with arterial hypertension, ischemic heart disease, diabetes mellitus, and obesity (metabolic syndrome); it is more frequent in women than men and shows a strong increase in prevalence with age. Hearts of patients with HFpEF are generally not dilated, wall thickness is enlarged (hypertrophy), and left atrial size often is enlarged as a sign of chronically elevated end-diastolic pressures. Central to the pathophysiology of HFpEF is, presumably, compromised diastolic relaxation of the left ventricle, which causes congestion of the lung, shortness of breath, or pulmonary edema. Clinical decompensation is often associated with strongly elevated blood pressure.

Molecular alterations include increased myocardial fibrosis (causing a permanent relaxation deficit) as well as more dynamic changes, such as reduced phosphorylation of titin, the sarcomeric protein that spans the large region from the Z to the M band. Titin contains several molecular spring domains whose elastic modulus determines the passive tension of cardiomyocytes, particularly at low-to-medium levels of stretch. At higher levels of stretch, the extracellular matrix becomes involved. Titin stiffness is determined by its isoforms and by cGMP-dependent phosphorylation, suggesting that agents that increase cellular cGMP might be beneficial in HFpEF. However, the PDE5 inhibitor sildenafil, which preserves and elevates cellular cGMP in some cells (see Chapters 3, 31, and 45), failed to show benefit (Redfield et al., 2013). This lack of efficacy is, unfortunately, also true for all other pharmacological interventions in HFpEF, including ACEIs, ARBs, and spironolactone. Exercise training is presently the only intervention that significantly increases maximal physical activity in HFpEF patients. In the absence of evidence-based clinical trial data, current therapy recommendations concentrate on optimal treatment of the underlying diseases, such as hypertension, diabetes, and obesity.

Heart Failure Staging

Heart failure was one of the first diseases for which guidelines described specific therapies for each stage of the disease. An early classification of the stages of heart failure was that of the NYHA, a classification still in use: class I (left ventricular dysfunction, no symptoms); class II (symptoms at medium-to-high levels of physical exercise); class III (symptoms at low levels of physical exercise); and class IV (symptoms at rest or daily life...
physical activities such as brushing teeth). The more recent guidelines of the AHA and ACC extended this classification by taking into account that

- heart failure is part of the cardiovascular continuum with preventable risk factors (stage A)
- an asymptomatic stage exists that requires treatment to delay transition to symptomatic heart failure (stage B)
- patients oscillate between different degrees of symptoms and therefore between class II and III (class C, which generally includes NYHA class II/III patients)
- a final stage of the disease requires different treatment and special considerations, such as heart transplantation and left ventricular assist device implantation (stage D).

This chapter uses the AHA/ACC classification (Yancy et al., 2013) but also considers the recent guidelines of the European Society of Cardiology (Ponikowski et al., 2016), which provide more specific treatment algorithms, and the 2016 AHA/ACC update (Yancy et al., 2016). Treatment guidelines are summarized in Figure 29–3.

**Prevention and Treatment**

Ischemic heart disease, hypertension, and valvular diseases are the most prevalent causes of heart failure. People at high risk (stage A) should therefore be consequently treated with drugs with an established effect on the natural course of these diseases, in conjunction with appropriate lifestyle changes. Studies in thousands of patients have reproducibly shown that blood pressure lowering in hypertensive patients and lipid-lowering with statins in dyslipidemic patients reduce not only the incidence of myocardial infarction and death but also the incidence of heart failure. The data are weaker for antidiabetic drugs, but consensus exists that blood glucose should be controlled with a hemoglobin A₁c goal of 7%–7.5%.

Treatment of heart failure has seen a dramatic change over the past decades. Until the late 1980s, drugs and drug dosing were symptom oriented and based on pathophysiological considerations of acute systolic heart failure. Treatment was mainly directed toward symptom relief and short-term improvement of hemodynamic function. With the era of

Figure 29–3  AHA/ACC 2013 Heart Failure Treatment Guidelines: stages in the development of HF and recommended therapy by stage. (See Yancy et al., 2013 and 2016, for details.)
Drugs for the treatment of chronic heart failure should reduce the morbidity and mortality, much of the former beliefs have proven to be wrong. For example, positive inotropic drugs (sympathomimetics and PDE inhibitors) that exert acute symptomatic benefit reduce life expectancy when given chronically. In contrast, β blockers decrease cardiac output acutely and may make people feel weak at the start of therapy but prolong life expectancy when given in increasing doses for extended periods. Vasodilators once seemed a logical choice for heart failure, but pure vasodilators such as the α receptor antagonist prazosin or the nitrate ISDN, in combination with the vasodilator hydralazine, do not positively affect the prognosis in Caucasians (see further discussion). Thus, clinical trials have established important principles for assessing efficacy of therapies for heart failure:

1. Drugs for the treatment of chronic heart failure should reduce the patient morbidity and mortality.
2. Short-term drug effects poorly predict the outcome of randomized clinical trials and optimal therapies for heart failure.
3. Considerations of stage of disease are critical.
4. New drugs for heart failure should be compared to the most effective current combination therapy, a principle often ignored in preclinical animal work.
5. Nonpharmacological treatment options such as cardiac resynchronization devices and intracardiac defibrillator/cardioverters are important for their documented lifesaving effect in selected patient populations.

Attention to these principles for assessing long-term efficacy of heart failure therapies has provided evidence-based principles of treatment.

### Drug Treatment of Chronic Systolic Heart Failure (Stages B and C)

#### Treatment Principle I: Neurohumoral Modulation

Dampening neurohumoral activation and its deleterious consequences on the heart, blood vessels, and kidney is the cornerstone of heart failure therapy. Therapy consists of ACEIs/ARBs, β blockers, and MRAs. Further activation of the natriuretic peptide system adds benefit (Figure 29–1). A systematic discussion of the drugs is found in Chapters 12, 25, 26, 27, and 28.

#### Angiotensin-Converting Enzyme Inhibitors

Angiotensin II, the most active angiotensin peptide, is largely derived from angiotensinogen in two proteolytic steps. First, renin, an enzyme released from the kidneys, cleaves the decapeptide AngI from the amino terminus of angiotensinogen (renin substrate). Then, ACE removes a carboxy-terminal dipeptide (His9-Leu10) from AngI, yielding the active octapeptide, AngII (Figure 26–1). Thus, ACEIs not only act as inhibitors of AngII, but also reduce aldosterone levels and thereby act as indirect diuretics, have direct antiremodeling effects on the heart, and produce sympatholytic effects (thus moderating the reflex tachycardia that accompanies vasodilation and the lowering of blood pressure).

### Historical Perspective

A series of landmark studies over three decades has established the current thinking on the treatment of patients with chronic HF-REF. These studies are not reviewed here, but interested readers may wish to consult the evidence that supports current therapies. These studies, often indicated by an acronym, are summarized in Table 29–1.
The ACEIs have important renal effects. When renal perfusion pressure is reduced, AngII constrains renal efferent arterioles, and this serves to maintain glomerular filtration pressure and GFR. Thus, under circumstances in which renal perfusion pressure is compromised, inhibition of the RAAS may induce a sudden and marked decrease in GFR. For this reason, ACEIs are contraindicated in bilateral renal artery stenosis. Likewise, because patients with heart failure often have low renal perfusion pressures, aggressive treatment with ACEIs may induce acute renal failure. To avoid this, for patients with heart failure patients, ACEIs should be initiated at very low doses; blood pressure, blood creatinine, and K+ levels should be monitored; and the ACEI dose slowly increased over weeks toward target levels (for agents that have been carefully evaluated in clinical trials; Table 29–2). The potentially dangerous acute effects become beneficial with long-term use of ACEIs because the (small) chronic lowering of glomerular pressures protects the glomerulus from fibrotic degeneration.

The ACEI-induced lowering of aldosterone levels causes reduced expression of the aldosterone-dependent epithelial Na+ channel (ENaC) in the distal tubule (see Figure 25-6). This target of K+-spARING diuretics (see discussion that follows) normally mediates Na+ reabsorption and K+ excretion. Lower levels of ENaC lead to less absorption of Na+ and less excretion of K+. Thus, ACEIs favor hyperkalemia, which can be detrimental in patients with renal insufficiency but is normally beneficial for patients with heart failure who more often present with hypokalemia, a condition that promotes cardiac arrhythmias. ACEIs shift the balance of vascular smooth muscle tone toward vasodilation and thereby increase renal blood flow, another reason for their chronic protective effects on the kidney. This effect also explains why NSAIDs, which reduce the production of vasodilating prostaglandins, antagonize effects of ACEIs and should be avoided in patients with heart failure.

**Other Actions, Good and Adverse.** Angiotensin-converting enzyme has other actions, including the inactivation of bradykinin and substance P. ACEIs increase bradykinin and substance P levels, with two prominent consequences: cough, the most frequent ADR (~5%); and angioedema. A rare (~0.7%), but life-threatening condition presenting with swelling of the skin and mucous membranes of the throat and asphyxia (three times more common amongst African Americans). Experimental evidence suggests that increases in bradykinin contribute to the therapeutic efficacy of ACEIs and may explain why ARBs, which do not increase bradykinin (and therefore cause no cough), have not been consistently associated with improved survival in patients with HFrEF (Ponikowski et al, 2016). The ACEIs are generally well tolerated in the majority of patients. Important ADRs are the following:

- dry cough, necessitating a change to ARBs;
- creatinine plasma concentration increase (~<20%, normal; 20%–50%: careful observation and reduction of ACEI dosage; > 50%, stop ACEI and consult specialist for diagnosis of renal artery);
- hyperkalemia (small increase normal, but requires careful observation in patients with diabetes, renal insufficiency, or comedication with MRA, K+-spARING diuretics, or NSAIDs);
- angioedema (stop drug immediately, treat with antihistamines, corticosteroids, or, in severe case, EPI); and
- allergic skin reactions.

**Angiotensin Receptor Antagonists**

The ARBs are systematically discussed in Chapter 26. They are highly selective, competitive receptor antagonists at the AT1 receptor, which mediates the major effects of AngII. They are therapeutic alternatives to ACEIs and second choice in all stages of heart failure in patients who do not tolerate ACEIs. Given the central role of the AT1 receptor for the actions of AngII, it is not surprising that ARBs show the same pharmacological profile as ACEIs with the exception of not inducing cough. The unopposed activity of AT2 receptor pathways in the presence of AT1 blockade by an ARB seems to confer no therapeutic advantage to ARBs over ACEIs. Moreover, the addition of an ARB to therapy with an ACEI does not affect the prognosis of patients with heart failure but does increase hypotension, hyperkalemia, and renal dysfunction. A negative interaction between ACEIs and ARBs appears to extend to patients with higher renal risk. There is, therefore, no routine indication for this combination.

**β Adrenergic Receptor Antagonists**

**Major Effects of β Adrenergic Antagonists.** The sympathetic neurotransmitters NE (released at adrenergic nerve varicosities) and EPI (secreted by the adrenal medulla) are strong stimuli of heart function. They increase heart rate (positive chronotropic effect) and force of contraction (positive inotropic effect) and thereby augment cardiac output. They quicken the rate of force development (increased +dP/dt, positive inotropy) and accelerate cardiac muscle relaxation (greater -dP/dt, positive lusitropic effect) which aids ventricular filling during diastole. Acceleration of the atrial-ventricular conduction rate (positive dromotropic effect) shortens the heart cycle and allows higher beating rates. Catecholamines enhance cardiac myocyte automaticity and lower the

THERAPY OF HEART FAILURE

gluconeogenesis (β2), and, importantly, stimulation of renin release from the macula densa (β1). Thus, activation of the SNS coactivates the RAAS, and, as outlined previously, activation of the RAAS activates the SNS by stimulation of NE release (see Chapters 12 and 26).

The β blockers competitively reduce β receptor–mediated actions of catecholamines and thus, depending on the activation level of the SNS, reduce heart rate and force, slow relaxation, slow AV conduction, suppress arrhythmias, lower renin levels, and, depending on their selectivity for the β1 receptor, permit more or less bronchoconstriction, vasoconstriction, and lowering of hepatic glucose production.

**Why Use β Blockers in Heart Failure?** In light of the above actions, the efficacy of β blockers in heart failure came as a surprise and had to overcome resistance in the medical community. How can a drug with cardiovascular effects on heart function be beneficial in a clinical situation in which the heart is already dysfunctional and depending on catecholamines to maintain cardiac output? The first therapeutic application of β blockers at low doses was to a Swedish cohort of patients with heart failure with cardiac decompensation and heart rate greater than 120 beats/min; the goal was to reduce heart rate and cardiac energy consumption (Waagstein et al., 1975). The success of the experiment led to large clinical studies that showed an impressive 35% prolongation of life expectancy in patients treated with β blockers (Table 29-1), on top of effects of ACEIs, diuretics, and digoxin.

Key to the understanding of the success of β blockers in heart failure were two lessons. First, therapy must be initiated in a clinically stable condition and at very low doses (1/8 of target), and dose escalation requires time (e.g., doubling every 4 weeks in ambulatory settings; “start low, go slow”). Under these conditions, the heart has time to adapt to decreasing stimulation by catecholamines and to find a new equilibrium at a lower adrenergic drive. Importantly, β blockers do not fully block the receptors; rather, they are competitive antagonists that shift the concentration-response curve of catecholamines to the right (see Figure 3–4).

Second, although the acute effects of catecholamines can be lifesaving, that level of β adrenergic stimulation applied chronicly, as the SNS does in response to heart failure, is deleterious. Positive chronotropic, inotropic, and lusitropic effects all come at the price of overproportional increase in energy consumption. This is irrelevant in situations of acute blood loss or other stresses, but critical if persistent. The heart reacts to chronic sympathetic stimulation by a heart failure–specific gene program (e.g., down-regulation of β adrenergic receptor density; upregulation of inhibitory G proteins; and decreases of SR Ca2+–ATPase, the fast isoform of myosin heavy chain, and repolarizing K+ currents), changes that come at the price of decreased dynamic range and increased propensity for arrhythmias. Reversal of the heart failure gene program by β blockers (Lowes et al., 2002) likely contributes to the paradoxical increase in left ventricular EF after 3–6 months of therapy and to the reduced rate of arrhythmogenic sudden cardiac death noted in the large studies. In a simple view, β blockers protect the heart from the adverse long-term consequences of adrenergic overstimulation, for example, increased energy consumption, fibrosis, arrhythmias, and cell death. Lower heart rates not only save energy but also improve contractile function because the failing heart, in contrast to the healthy human heart, has a negative force-frequency relation (Pieske et al., 1995). In addition, β blockers improve perfusion of the myocardium by prolonging diastole, thereby reducing ischemia.

**Available Agents.** Four β blockers have been successfully tested in randomized clinical trials (Table 29-1): the β1-selective agents metoprolol (MERIT-HF Investigators, 1999) and bisoprolol (CIBIS-II Investigators, 1999) and the third-generation agents with additional actions, carvedilol and nebivolol. Carvedilol is a nonselective β blocker and an α1 receptor antagonist. Nebivolol (Flather et al., 2005) is β1 selective and has additional vasodilatory actions that may be NO mediated (Figure 12–4; Table 12–4). Early evidence of superiority of carvedilol over metoprolol (Poole-Wilson et al., 2003) has not been confirmed.

**Pharmacokinetic Considerations.** There are important pharmacokinetic differences amongst these β blockers (Table 29–3), distinctions that are relevant because successful therapy of heart failure (and most other chronic cardiovascular diseases) requires stable plasma concentrations over the entire day (trough levels before next dose application > 50% of maximum).

Metoprolol has a too short $t_{1/2}$ (3–5 h) and should be prescribed only as the zero-order prolonged-release formulation used by all successful clinical studies. Standard extended-release formulations likely do not suffice. A further disadvantage of metoprolol is its dependency on the polymorphic CYP2D6 for its metabolism. CYP2D6 “poor metabolizers,” about 8% of the Caucasian population, exhibit CYP2D6 levels of metoprolol 5-fold higher than those of standard metabolizers; in a prospective longitudinal study, that difference correlated with 2-fold differences in heart rate responses (Rau et al., 2009). Bisoprolol has a sufficiently long plasma $t_{1/2}$ (10–12 h) for once-daily dosing and is not metabolized by CYP2D6. Carvedilol has a shorter $t_{1/2}$ (6–10 h) and requires twice-daily dosing. An advantageous peculiarity of carvedilol is that it dissociates only slowly from β receptors and therefore acts longer than its plasma $t_{1/2}$ suggests. Carvedilol metabolism depends on CYP2D6, but less so than metoprolol. Nebivolol plasma concentrations are 10- to 15-fold higher in CYP2D6 poor metabolizers, but this is without clinical consequence, likely because the first metabolite is similarly active as the parent compound. Nebivolol is not approved in the U.S. for the treatment of heart failure, but it is approved in 71 countries worldwide, including Europe (patients > 70 years of age).

**Clinical Use.** All patients with symptomatic heart failure (stage C, NYHA II–IV) and all patients with left ventricular dysfunction (stage B, NYHA I) after myocardial infarction should be treated with a β blocker. The therapy with β blockers should be initiated only in clinically stable patients at very low doses, generally 1/8 of the final target dose, and titrated upward every 4 weeks. Even when initiated properly, a tendency to retain fluid exists that may require diuretic dose adjustment. The improvement of left ventricular function generally takes 3–6 months, and in this period, patients should be carefully monitored.

The β blockers should not be administered in new-onset or acutely decompensated heart failure. If patients are hospitalized with acute decompensation under current therapy with β blockers, doses often have to be

CYP2D6 indicates dependence on polymorphic CYP2D6 metabolism, likely less relevant for nebivolol because the first metabolite is active.

*Clinical studies in heart failure have mainly used metoprolol succinate in a slow-release formulation (zero order of kinetics); metoprolol, itself, has a $t_{1/2}$ of 3–5 h.
reduced or the drug discontinued until clinical stabilization, after which therapy should again be initiated.

Precautions. Formally, β blockers have long lists of adverse drug responses and contraindications. Practically, however, they are generally well tolerated if properly initiated. If doses are increased too rapidly, fall of blood pressure, fluid retention, and dizziness are common and require dose reduction.

The major cardiovascular responses associated with use of β blockers are the following:

- Heart rate lowering, a desirable effect that indicates proper dosing (no decrease indicates insufficient dosing). A reasonable target resting heart rate is 60–70/min.
- AV block (beware preexisting conduction disturbance; consider pacemaker implantation).
- Bronchoconstriction. Allergic asthma is a contraindication for all β blocker use; however, chronic obstructive lung disease is not, because the β₂ receptor–dependent dynamic range is low in these patients, and studies have documented safety. Nonetheless, only β₁-selective compounds should be used in patients with chronic obstructive pulmonary disease.
- Peripheral vasoconstriction (cold extremities). Initial vasoconstriction turns into vasodilation under chronic therapy with β blockers. Cold extremities are generally not a problem in patients with heart failure. Yet, patients with peripheral artery disease or symptoms of claudication or Raynaud disease should be carefully monitored and treated with carvedilol if a β blocker is employed.

Mineralocorticoid Receptor Antagonists

The third group of drugs with a documented life-prolonging effect in patients with heart failure is MRAs. They should be given in low doses to all patients in stage C (NYHA class II–IV), that is, with symptomatic HFrEF, despite the fact that the combination of ACEIs/ARBs, and MRA is formally contraindicated due to the risk of hyperkalemia. The safety of a low-dose MRA (25 mg vs. a standard of 100 mg spironolactone) was demonstrated in a large randomized trial in a patient cohort with severe heart failure (NYHA III–IV), with the MRA added to ACEIs, diuretics, and digoxin (Pitt, 2004). Later studies with eplerenone in less-severe heart failure essentially confirmed the efficacy of this class of drugs.

Mechanism of Action. The MRAs act as antagonists of nuclear receptors of aldosterone (Figure 25–6). They are K⁺-sparking diuretics (see discussion that follows) but gained more importance in the treatment of heart failure for their additional efficacy in suppressing the consequences of neurohumoral activation. Aldosterone, as the second major actor of the RAAS, promotes Na⁺ and fluid retention, loss of K⁺ and Mg²⁺, sympathetic activation, parasympathetic inhibition, myocardial and vascular fibrosis, baroreceptor dysfunction, and vascular damage, all adverse effects in the setting of heart failure. Aldosterone plasma levels decrease under therapy with ACEIs or ARBs, but quickly increase again, a phenomenon called aldosterone escape. It is likely explained by incomplete blockade of the RAAS (e.g., AngI can be converted to AngII by chymase, in addition to ACE; see Figure 26–1) and by the fact that aldosterone secretion is regulated not only by AngII but also by sodium and potassium plasma Na⁺ and K⁺. MRAs inhibit all the effects of aldosterone, of which the reduction in fibrosis is most pronounced in animal models.

Clinical Use; Adverse Responses. Currently, two MRAs are available, spironolactone and eplerenone. Only eplerenone is FDA-approved for the therapy of heart failure because no economic interest exists for the approval of spironolactone, which is free of patent protection. Nevertheless, guidelines recommend both. Spironolactone is a nonspecific steroid hormone receptor antagonist with similar affinity for progesterone and androgen receptors; it causes gynecomastia (painful breast swelling, 10% of patients) in men and dysmenorrhea in women. Eplerenone is selective for the mineralocorticoid receptor and therefore does not cause gynecomastia.

The most important ADR of both MRAs is hyperkalemia. Under the well-controlled conditions of clinical trials, serious hyperkalemia (>5.5 mmol/L) occurred in 12% in the eplerenone group and in 7% in the placebo group (Zannad et al., 2011). Rates may be higher in clinical practice when risk conditions, comedication, and dose restrictions are not well controlled (Juurink et al., 2004). Guidelines for the use of MRAs in patients with heart failure are:

- Administer no more than 50 mg/d.
- Do not use if the GFR is less than 30 mL/min (creatinine = 2 mg/dL).
- Be careful with elderly patients, in whom improvement in prognosis may be less relevant than prevention of serious side effects.
- Be careful with diabetics, who carry a higher risk of hyperkalemia.
- Do not combine with NSAIDs, which are contraindicated in heart failure but are frequently prescribed for chronic degenerative diseases of the musculoskeletal system.
- Do not combine with other K⁺-sparking diuretics.

Angiotensin Receptor and Neprilysin Inhibitors

The latest addition to standard combination therapy of heart failure is sacubitril/valsartan. It is made by recrystallizing the well-known ARB valsartan with sacubitril, a prodrug that, after deesterification, inhibits neprilysin, a peptidase mediating the enzymatic degradation and inactivation of natriuretic peptides (ANP, BNP, CNP), bradykinin, and substance P. Thus, the drug combines inhibition of the RAAS with activation of a beneficial axis of neurohumoral activation, the natriuretic peptides. Consequently, the ARNI is expected to promote the beneficial effects of natriuresis, diuresis, and vasodilation of arterial and venous blood vessels and to inhibit thrombosis, fibrosis, cardiac myocyte hypertrophy, and renin release. Augmentation of ANP/BNP levels by inhibiting degradation is probably a better pharmacological principle than giving the agonist BNP (neseritide; see under acute heart failure) directly because it enhances endogenous regulation of plasma and tissue levels. Sacubitril/valsartan causes smaller increases in bradykinin and substance P than omapatrilat, an earlier drug combining a neprilysin inhibitor and an ACEI. This difference may explain why sacubitril/valsartan is not associated with an increased rate of angioedema, the adverse effect that stopped the development of omapatrilat. A large head-to-head comparison study in patients with stable heart failure showed superiority of sacubitril/valsartan over enalapril (McMurray et al., 2014).

Treatment Principle II: Preload Reduction

Fluid overload with increased filling pressures (increased preload) and dilation of the ventricles in heart failure is the consequence of decreased kidney perfusion and activation of the RAAS. Normally, increased preload and stretch of the myofilaments increase contractile force in an autoregulatory manner, the positive force-length relationship or Frank-Starling mechanism. However, the failing heart in congestion operates at the flat portion of this relationship (Figure 29–4) and cannot generate sufficient force with increasing preload, leading to edema in the lungs and the periphery.

Diuretics increase Na⁺ and water excretion by inhibiting transporters in the kidney and thereby improve symptoms of CHF by moving patients to lower cardiac filling pressures along the same ventricular function curve. Diuretics are an integral part of the combination therapy of symptomatic forms of heart failure. Prognostic efficacy of diuretics in heart failure will remain an academic question, simply because randomization for a trial of diuretics would be ethically impermissible. Diuretics should not be given to patients without congestion because they activate the RAAS and may accelerate a vicious downward spiral. On the other hand, in severe heart failure, diuretic resistance may occur for various reasons and cause clinical deterioration (Table 29–4).

Loop Diuretics

Loop diuretics (furosemide, torasemide, bumetanide; Table 29–5) inhibit the Na⁺–K⁺–2Cl⁻ symporter in the ascending limb of the loop of Henle, where up to 15% of the primary filtrate (~150 L/d) is reabsorbed, explaining their strong diuretic action. The increase in Na⁺ and fluid delivery to distal nephron segments has two consequences:

- It is sensed in the macula densa and normally activates tubuloglomerular feedback to decrease GFR. This autoregulation explains the quick

CHAPTER 29
THERAPY OF HEART FAILURE

It leads to increased ENaC-mediated reabsorption of Na+ and, in patients to lower cardiac filling pressures along the same ventricular function curve. Diuretics (D) improve symptoms of CHF by moving such as CGs or dobutamine, move patients to a higher ventricular function curve (lower dashed line), resulting in greater cardiac work for a given level of ventricular filling pressure. Vasodilators (V), such as ACEIs or nitroprusside, move patients to improved ventricular function curves while reducing ventricular filling pressure. Aggressive diuretic or vasodilator therapy, therefore, should have beneficial effects on patients with heart failure by reducing afterload and allowing the heart to expel blood against lower resistance. However, clinical trials with pure vasodilators were mainly disappointing, whereas inhibitors of the RAAS, vasodilators with a broader mode of action, were successful.

The bioavailability of orally administered furosemide ranges from 40% to 70%. High drug doses are often required to initiate diuresis in patients with worsening symptoms or in those with impaired GI absorption, as may occur in severely hypervolemic patients with CHF-induced GI edema. Oral bioavailabilities of bumetanide and torasemide are greater than 80%, and as a result, these agents are more consistently absorbed than furosemide. Furosemide and bumetanide are short-acting drugs.

loss of efficacy of older diuretics of the carbonic anhydrase inhibitor class (e.g., acetazolamide), acting in the proximal tubule. Thiazides (see discussion that follows) are derived from this class and cause a small decrease in the GFR. Loop diuretics inhibit the feedback mechanism because it is mediated by the Na+-K+-2Cl- symporter; they exhibit stable action and do not affect the GFR.

It leads to increased ENaC-mediated reabsorption of Na+ and, in exchange, to more K+ excretion in the distal tubule, explaining the main side effect, hypokalemia.

The fixed-combination formulation in use contains 37.5 mg hydralazine and 20 mg ISDN and is uptitrated to a target dose of 2 tablets, thrice a day.

Thiazide diuretics
Thiazide diuretics (hydrochlorothiazide, chlorothalidone; Table 29–5) have a limited role in heart failure for their low maximal diuretic effect and loss of efficacy at a GFR below 30 mL/min. However, combination therapy with loop diuretics is often effective in those refractory to loop diuretics alone, as refractoriness is often caused by upregulation of the Na+-Cl cotransporter in the distal convoluted tubule, the main target of thiazide diuretics (see Chapter 25).

Treatment Principle III: Afterload Reduction
The failing heart is exquisitely sensitive to increased arterial resistance (i.e., afterload) (Figure 29–5). Vasodilators, therefore, should have beneficial effects on patients with heart failure by reducing afterload and allowing the heart to expel blood against lower resistance. However, clinical trials with pure vasodilators were mainly disappointing, whereas inhibitors of the RAAS, vasodilators with a broader mode of action, were successful. Likely reasons include reflex tachycardia and tachyphylaxis (prazosin, ISDN) and negative inotropic effects (dihydropyridine calcium channel antagonists).

Hydralazine–Isosorbide Dinitrate
A remarkable exception is the therapeutic effect of a fixed combination of hydralazine and ISDN. In a pioneering trial, Cohn and colleagues showed improved survival in this combination in patients with heart failure (Cohn et al., 1986). The benefit was restricted to improvement in the cohort of African Americans. In a second trial in African Americans only, the combination conferred a 43% survival benefit (Taylor et al., 2004). It was FDA-approved in 2006, the first ethnically restricted approval.

As an orally available organic nitrate, ISDN, similar to GTN and ISMN, preferentially dilates large blood vessels, for instance, venous capacitance and arterial conductance vessels (Chapter 27). The main effect is "venous pooling" and reduction of diastolic filling pressure (preload) with little effect on systemic vascular resistance (which is regulated by small- to medium arteries). Sustained monotherapy is compromised by nitrate tolerance (i.e., loss of effect and induction of a pro-constrictory state with high levels of ROS). Hydralazine is a direct vasodilator whose mechanism of action remains unresolved (Chapter 28). It was suggested that hydralazine prevents nitrate tolerance by reducing ROS-mediated inactivation of NO (Munzel et al., 2005), an action that could explain the efficacy of this drug combination in heart failure amongst African Americans. A test of this hypothesis in patients with NYHA class II–III heart failure (Chirkov et al., 2010) failed to confirm the hypothesis. The relevant differences in responsiveness between African American and Caucasian patients with heart failure have not been explained.

The fixed-combination formulation in use contains 37.5 mg hydralazine and 20 mg ISDN and is uptitrated to a target dose of 2 tablets, thrice a day.
they shift the sigmoidal relationship between free Ca$^{2+}$ concentration and force to the left.

ure–associated hospitalizations without increasing mortality (Table 29–1). They have been associated with lupus erythematosus.

Cardiac myocytes contract and develop force in response to membrane depolarization and subsequent increases in intracellular Ca$^{2+}$ concentrations (Figure 29–6). The mechanisms of this excitation-contraction coupling are the basis for understanding the mode of action of positive inotropic drugs. Cardiac myocytes respond to increases in intracellular Na$^{+}$ by increasing the concentration of free intracellular Ca$^{2+}$ ([Ca$^{2+}$]), Ca$^{2+}$ sensitizers (e.g., levosimendan) sensitize myofilaments to Ca$^{2+}$; that is, they shift the sigmoidal relationship between free Ca$^{2+}$ concentration and force to the left.

Cardiac myocytes contract and develop force in response to membrane depolarization and subsequent increases in intracellular Ca$^{2+}$ concentrations (Figure 29–6). The mechanisms of this excitation-contraction coupling are the basis for understanding the mode of action of positive inotropic drugs and cardiac myocyte function in general. Most currently employed positive inotropes and novel compounds in development act by increasing the concentration of free intracellular Ca$^{2+}$ ([Ca$^{2+}$]). Ca$^{2+}$ sensitizers (e.g., levosimendan) sensitize myofilaments to Ca$^{2+}$; that is, they shift the sigmoidal relationship between free Ca$^{2+}$ concentration and force to the left.

Contractility

Inotropic Agents and the Regulation of Cardiac Contractility

The failing heart is unable to generate force sufficient to meet the needs of the body for perfusion of oxygenated blood (Figure 29–1). Historically, physicians attempted to stimulate force generation with positive inotropic drugs. Unfortunately, when used chronically, these agents do not improve life expectancy or cardiac performance. Rather, chronic use of positive inotropes is associated with excess mortality. Of the available inotropic agents, only CGs are used in the treatment of chronic heart failure; this is for two reasons: history and one large trial in patients with NYHA class II–III heart failure showing that digoxin reduced the rate of heart failure–associated hospitalizations without increasing mortality (Table 29–1).

**Intotropes and the Regulation of Cardiac Contractility**

Cardiac myocytes contract and develop force in response to membrane depolarization and subsequent increases in intracellular Ca$^{2+}$ concentrations (Figure 29–6). The mechanisms of this excitation-contraction coupling are the basis for understanding the mode of action of positive inotropic drugs and cardiac myocyte function in general. Most currently employed positive inotropes and novel compounds in development act by increasing the concentration of free intracellular Ca$^{2+}$ ([Ca$^{2+}$]). Ca$^{2+}$ sensitizers (e.g., levosimendan) sensitize myofilaments to Ca$^{2+}$; that is, they shift the sigmoidal relationship between free Ca$^{2+}$ concentration and force to the left.

**Na$^{+}$/K$^{+}$ ATPase Inhibitors.** Cardiac glycosides inhibit the plasma membrane Na$^{+}$/K$^{+}$ ATPase, a key enzyme that actively pumps Na$^{+}$ out and K$^{+}$ into the cell and thereby maintains the steep concentration gradients of Na$^{+}$ and K$^{+}$ across the plasma membrane. Inhibition of this enzyme slightly reduces the Na$^{+}$/K$^{+}$ gradient across the myocyte membrane, reducing the driving force for Ca$^{2+}$ extrusion by the NCX, thereby providing more Ca$^{2+}$ for storage in the SR and subsequent release to activate contraction. The details are explained by Figure 29–6 and its legend.

**cAMP-Dependent Inotropes.** The strongest stimulation of the heart is achieved by receptor-mediated stimulation of adenylyl cyclase. This explains the use of dobutamine, EPI, and NE in cardiogenic shock (see discussion that follows). Inhibition of cAMP degradation by PDE inhibitors such as milrinone or enoximone elevates cellular cAMP concentrations and activates the cAMP-PKA pathway and other cAMP-responsive systems (see Chapter 3). This concerted action results in higher peak Ca$^{2+}$ concentrations in systole and thereby peak force (Figure 29–6). All cAMP-dependent inotropes hasten contraction (positive clonitropic effect) and relaxion (positive lusitropic effect), allowing sufficient perfusion of the ventricles in diastole under catecholamine stimulation and with the concomitant tachycardia. On the downside, acceleration of contraction during catecholamine stimulation, by promoting net Ca$^{2+}$ entry per unit of time, increases the utilization of ATP for Ca$^{2+}$ reuptake into the SR via the SERCA and to restore the membrane potential by the activity of the Na$^{+}$/K$^{+}$ ATPase.

**Myofilament Ca$^{2+}$ Sensitizers.** Calcium sensitizers increase the affinity of the myofilaments for Ca$^{2+}$, for example, by inducing a conformational change in TnC. They enhance force for a given [Ca$^{2+}$], and do not elevate [Ca$^{2+}$], with its potentially deleterious pro-arrhythmic and energy-increasing consequences. But, increased myofilament Ca$^{2+}$ sensitivity also causes reduced dissociation of Ca$^{2+}$ from the myofilaments in daily. Patients will also generally be taking a β blocker. Hypotension may be dose limiting. Frequent adverse effects include dizziness and headache. Adherence to the thrice-daily dosing regimen may impose practical problems (Cohn et al., 1986), and hydralazine doses greater than 200 mg have been associated with lupus erythematosus.

**Treatment Principle IV: Increasing Cardiac Contractility**

The details are explained by Figure 29–6 and its legend.
THERAPY OF HEART FAILURE

Due to increased myosin light chain phosphorylation. The positive inotropic effect can aggravate the already-compromised diastolic function in heart failure. It could also lead to delayed Ca\(^{2+}\) release from myofilaments in diastole and prolongation of relaxation (“negative lusitropic effect”). This effect can aggravate the already-compromised diastolic function in heart failure. It could also lead to delayed Ca\(^{2+}\) release from myofilaments in diastole and arrhythmias (Schober et al., 2012). Calcium sensitizers failed to improve prognosis in clinical trials of patients with chronic heart failure. However, levosimendan is approved in some countries for the treatment of acute heart failure. It has additional selective and potent inhibitory effects on PDE III, whose positive lusitropic consequence appears to antagonize the negative lusitropic effect of Ca\(^{2+}\) sensitization. Agonists of G\(_i\)-coupled receptors (\(\alpha\), AT\(_1\), ET\(_1\)) also increase myocardial Ca\(^{2+}\) sensitivity, likely due to increased myosin light chain phosphorylation. The positive inotropic effect is stronger than that of \(\beta\) receptor stimulation, develops more slowly, and is independent of cAMP.

Cardiac Glycosides

**Actions and Therapeutic Use of Digoxin.** Positive Inotropic Effect. CGs at therapeutic concentrations mildly inhibit the cardiac Na\(^+/K^+\) ATPase, causing an increase in intracellular \([Na^+]\). Increased \([Na^+]\), inhibits Ca\(^{2+}\) extrusion via the NCX resulting in higher intracellular \([Ca^{2+}]\) and enhanced contractility (Figure 29–6). The increased contractility and hence cardiac output provides symptomatic relief in patients with heart failure (Figure 29–1). With the main trigger for neurohumoral activation removed, sympathetic nerve tone and, consequently, heart rate and peripheral vascular resistance drop. These decreases in preload and afterload reduce chamber dilation and thereby wall stress, a strong determinant of myocardial \(O_2\) consumption. Increased renal perfusion lowers renin production and increases diuresis, further decreasing preload.

**Electrophysiological Actions.** CGs at therapeutic concentrations shorten action potential durations by accelerating the inactivation of L-type Ca\(^{2+}\) channels due to higher \([Ca^{2+}]\). Shorter action potentials (= refractory period) favor reentry arrhythmias, a reason that CGs promote atrial fibrillation. With the loss of intracellular K\(^+\) and increase in intracellular Na\(^+\), the resting membrane potential (determined largely by the K\(^+\) current, now diminished) moves to less-negative values with two consequences. Diastolic depolarization and automaticity are enhanced, and, due to partial inactivation of Na\(^+\) channels, impulse propagation is strongly reduced. Both phenomena promote reentry arrhythmias. At even higher CG concentrations, SR Ca\(^{2+}\) overload reaches a point at which Ca\(^{2+}\) is spontaneously released at amounts large enough to initiate Ca\(^{2+}\) waves and, via the NCX, depolarization of the cell (Figure 29–6). The typical ECG signs at this stage of CG intoxication are extrasystoles and bigeminy with a high risk of ventricular fibrillation.

**Extracardiac Effects.** CGs also inhibit Na\(^+/K^+\) ATPase in other excitable tissues. (1) At low plasma concentrations, CGs stimulate vagal efferents and sensitize baroreceptor reflex mechanisms, causing increased parasympathetic and decreased sympathetic tone. The beneficial effect of digoxin at low plasma concentrations (Rathore et al., 2003), at which positive inotropic effects are minor, suggests that the neurohumoral actions of CGs may be therapeutically more relevant than the direct positive inotropic effects. (2) CGs at higher plasma concentrations increase Ca\(^{2+}\) concentrations in vascular smooth muscle cells and cause vasoconstriction. In patients with heart failure, vasodilation normally prevails due to the decrease in sympathetic nervous tone, but the direct vascular effect explains mesenteric artery ischemia or occlusion, a rare but severe adverse effect of CGs.

**Indirect Actions.** The vagotonic and sympatholytic effects of CGs cause bradycardia and AV prolongation (negative dromotropic effect) and can promote atrial flutter and fibrillation. Fibrillation is explained by the Ach-induced shortening of atrial action potentials, which is further enhanced by the direct CG effect described previously. On the other hand, CGs are therapeutically used for frequency control of permanent atrial fibrillation because of their negative dromotropic effects.

**Interactions With K\(^+\), Ca\(^{2+}\), and Mg\(^{2+}\).** Hyperkalemia reduces and hypokalemia increases the binding affinity of CG to the Na\(^+/K^+\) ATPase. In addition, hypokalemia reduces repolarizing K\(^+\) currents, with the consequence of increased spontaneous diastolic depolarization and automaticity. Hypokalemia is therefore a major risk factor for arrhythmogenic effects of CGs. Hypercalcemia as well as hypomagnesemia favor SR Ca\(^{2+}\) overload and spontaneous Ca\(^{2+}\) release events. Control of serum electrolytes is therefore mandatory.

**HISTORICAL PERSPECTIVE**

The British botanist William Withering (1741–1799) systematically described the actions of *Digitalis purpurea* in patients with heart failure (“dropsy”) and gave exact dosing recommendations (Skou 1986). Oswald Schmiedeberg (1833–1921), working in Strasbourg, France, isolated the first chemical entities from foxglove leaves; one of these entities was digitoxin. Until diuretics became available, CGs were the only heart failure drugs. CGs encompass many chemical entities, but only digoxin, its derivatives β-acetyl digoxin, methyldigoxin, and digitoxin are in clinical use in most countries. Until the 1980s, CGs were dosed according to therapeutic effects (e.g., improved diuresis [Withering considered CGs as diuretics], reduction of heart size [verifiable by X-ray], or alterations of the surface ECG) and to symptoms of overdosing, such as nausea and altered color perception (yellow-green). Now, serum digoxin concentrations can be measured by radioimmunoassay; Digoxin has therapeutic efficacy (including a small survival benefit) only at serum concentrations between 0.5 and 0.8 ng/mL (Rathore et al., 2003). Concentrations greater than 1.2 ng/mL are associated with increased mortality. Serum digoxin concentrations greater than 0.8 ng/mL should be avoided.
Adverse Effects. The therapeutic index of CG is extremely narrow, about 2, as documented in the DIG trial: plasma concentrations between 0.5 and 0.8 ng/mL are associated with beneficial effects, and concentrations of 1.2 ng/mL or greater are associated with a tendency toward increased mortality (Rathore et al., 2003). The most frequent and most serious adverse effects are arrhythmias. In CG overdosing, patients exhibit arrhythmias (90%), GI symptoms (~55%), and neurotoxic symptoms (~12%). The most frequent causes of toxicity are renal insufficiency and overdosing.

Cardiac toxicity in healthy persons presents as extreme bradycardia, atrial fibrillation, and AV block, whereas ventricular arrhythmias are rare. In patients with structural heart disease, frequent signs of CG toxicity are ventricular extrasystoles, bigeminy, ventricular tachycardia, and fibrillation. In principle, however, every type of arrhythmia can be CG induced. GI adverse effects are anorexia, nausea, and vomiting, mainly as a result of CG effects on chemoceptors in the area postrema. Spastic contraction of the mesenteric artery can rarely lead to severe diarrhea and life-threatening necrosis of the intestine. Headache, fatigue, and sleeplessness can be early symptoms of CG toxicity. Typical, albeit not too common (10%), are visual effects: altered color perception and coronas (halos). Some have speculated that the visual effects of digoxins intoxication contributed to the qualities of late paintings by Vincent van Gogh, who may have been treated for neurological complaints by Dr. Paul Gachet, whose portraits by van Gogh (painted in June 1890) show the doctor seated next to a sprig of the plant, a natural source of CGs and used widely in the 19th century (Lee, 1981).

Therapy of CG Toxicity. Cessation of CG medication normally suffices as therapy of CG toxicity. However, severe arrhythmias, such as extreme bradycardia or complex ventricular arrhythmias, require active therapy.

- Extreme sinus bradycardia, sinoatrial block, or AV block grade II or III: Atropine (0.5–1 mg) IV. If not successful, a temporary pacemaker may be necessary.
Treatment Principle V: Heart Rate Reduction

Heart rate is a strong determinant of cardiac energy consumption, and higher heart rates in patients with heart failure are associated with poor prognosis (Bohm et al., 2010). Partial agonists at β receptors such as xamoterol increase nocturnal heart rate (i.e., they prevent the physiological dip) and are associated with excess mortality in patients with heart failure (Xamoterol Study Group, 1990). Conversely, β blockers lower heart rate and improve survival prognosis.

Ivabradine

The circumstantial evidence for beneficial effects of heart rate lowering led to the development of ivabradine, a selective inhibitor of cardiac pacemaker channels (HCNs). The compound is approved in Europe for the treatment of heart failure and stable angina pectoris in patients not tolerating β blockers or in whom β blockers did not sufficiently lower heart rate (<75/min). Approval was based on a study showing a decrease in hospitalization and heart failure mortality, but not total or cardiovascular mortality (Swedberg et al., 2010). Of note, the effect of ivabradine was not superior to that of digoxin in an earlier study (Digitalis Investigation Group, 1997). In a recent large study in patients with stable angina (85% on β blockers), ivabradine conferred no benefit but led to phosphenes (typical transient enhanced brightness in a restricted area of the visual field) and increased the rate of bradycardia, atrial fibrillation, and QT prolongation (Fox et al., 2014), casting doubts about the role of the compound in ischemic heart disease. Ivabradine is not approved in the U.S.

Drug Treatment of Acutely Decompensated Heart Failure

Acutely decompensated heart failure is a leading cause of hospitalization in patients older than 65 and represents a sentinel prognostic event in the natural course of the disease, with a high recurrence rate and a 1-year mortality rate of about 30%. Even in decompensated heart failure, about 50% of patients exhibit preserved left ventricular function (HFrEF). The HFrEF cohort is older, more likely to be female and hypertensive, and with less coronary artery disease than the HFrEF cohort. Therapeutically, it is important to quickly identify and treat specific reasons for decompensation. These include, besides acute myocardial ischemia, uncorrected high blood pressure, atrial fibrillation and other arrhythmias, pulmonary embolism, and kidney failure, as well as several pharmacological reasons: nonadherence to heart failure medication and Na+/fluid restriction, negative inotropic drugs (e.g., verapamil, diltiazem, nifedipine, β blockers), and NSAIDs and COX-2 inhibitors.

The therapy of acutely decompensated heart failure aims at fast symptomatic relief, short-term survival, fast recompensation, and reduction of readmission rates. It is less evidence-based than the therapy of chronic heart failure, and no single drug given to patients experiencing acute decompensation has yet been shown to improve the long-term prognosis. The main principles (besides nonpharmacological treatment modalities such as O2 and noninvasive or [rarely] invasive ventilatory support) are diuretics and vasodilators, with positive inotropes in selected cases and mechanical support systems as an ultimate step.

Diuretics

Patients with dyspnea and signs of fluid overload/congestion should be promptly treated with an intravenous loop diuretic such as furosemide that exerts an acute vasodilator and slightly delayed but still fast diuretic effect. Optimal doses and regimens need to be adapted to the clinical picture. An intravenous bolus of 40–80 mg furosemide is a common starting dose, often continued by an infusion of furosemide at a daily dose equal to the (oral) daily dose prescribed before hospitalization. Doses may need to be escalated according to symptoms and diuresis. Additional use of a thiazide diuretic in small doses can break a relative resistance to loop diuretics but requires careful monitoring of K+ losses. Excessive doses of furosemide must be avoided because they can cause hypotension, a reduction in GFR, electrolyte disturbance, and further neurohumoral activation.

Vasodilators

Vasodilators such as nitroglycerin and nitroprusside reduce preload and afterload. The reduction in preload (= diastolic filling pressure) moves the patient to the left on the stroke volume-preload relationship, similar to the effect of diuretic-induced volume reduction (Figure 29–3). The accompanying reduction in chamber dimension reduces wall stress and thus O2 consumption. The additional reduction in afterload allows the heart to expel blood against a lower output resistance (Figure 29–4). These mechanisms explain why vasodilators (which have no inotropic efficacy and lower blood pressure) increase stroke volume. Yet, robust evidence for symptomatic benefit or improved clinical outcome is lacking. They are probably best suited for patients with hypertension and should be avoided in patients with systolic blood pressure less than 110 mm Hg (Poronkowski et al., 2016). The main risk is hypotension, which is negatively associated with favorable outcomes in patients with acutely decompensated heart failure (Patel et al., 2014).

Neseritide, recombinant human BNP, dilates arterial and venous blood vessels by stimulating the membrane-bound guanylyl cyclase to produce more cGMP. By this mechanism, it decreases preload and afterload and reduces pulmonary capillary wedge pressure. It is approved for the treatment of acutely decompensated heart failure in the U.S., but not in several European countries. Early clinical studies and a meta-analysis raised concerns that the use of neseritide was associated with an increased risk for renal failure and death when compared to a noninotrope control therapy (Sackner-Bernstein et al., 2005). This risk was not confirmed in a more recent study (O’Connor et al., 2011), but beneficial effects (dyspnea relief) were also modest.

Positive Inotropic Agents

Stimulating the heart’s force of contraction in a situation of critically diminished cardiac output may appear to be the most intuitive intervention. Yet, inotropes in acutely decompensated heart failure are associated with worse outcome and should therefore be restricted to patients with critically low cardiac output and perfusion of vital organs. Hypotension less than 85 mm Hg has been suggested as a practical limit (Poronkowski et al., 2016). Reasons for the adverse consequences of positive inotropes are probably complex. All inotropic agents increase cardiac energy expenditure (greater and faster force development ⇒ more ATP consumption ⇒ greater O2 demand), which carries the risk of diffuse cardiac myocyte death. In acutely decompensated heart failure, the risk is exaggerated by the low perfusion pressure, any preexisting coronary artery disease, and the likely presence of cardiac myocyte hypertrophy and myocyte–endothelial cell mismatch. Tachycardia, aggravated by many inotropes, adds to the problem by strongly increasing energy expenditure and reducing the time for coronary perfusion in diastole. All positive inotropes increase the risk of arrhythmias.

Dobutamine

Dobutamine is the β adrenergic agonist of choice for the management of patients with acute CHF with systolic dysfunction. Dobutamine has relatively well-balanced cardiac and vascular actions: stimulation of cardiac output with less tachycardia than EPI and with a concomitant decrease in pulmonary artery wedge pressure. Dobutamine is a racemic mixture of (−) and (+) enantiomers. The (−) enantiomer is a potent agonist at α1 adrenergic receptors and a weak agonist at β1 and β2 receptors. The (+) enantiomer is a potent β1 and β2 agonist without much activity at α1 adrenergic receptors. Dobutamine has no activity at dopamine receptors. At infusion rates that result in a positive inotropic effect in humans, the β1 adrenergic effect...
in the myocardium predominates. In the vasculature, the α1-adrenergic agonist effect of the (+) enantiomer appears to be offset by the vasodilating effects of the (-) enantiomer at α2 receptors. Thus, the principal hemodynamic effect of dobutamine is an increase in stroke volume from positive inotropy, augmented by a small decrease in systemic vascular resistance and, therefore, afterload. Lowering of pulmonary artery capillary pressure is considered an advantage compared to other catecholamines, as is the smaller chronotropic effect (reasons for which are not clear).

Continuous dobutamine infusions are typically initiated at 2–3 μg/kg/min and uptitrated until the desired hemodynamic response is achieved. Pharmacologic tolerance may limit infusion efficacy beyond 4 days; therefore, addition or substitution a PDE3 inhibitor may be necessary to maintain adequate circulatory support. The major side effects of dobutamine are tachycardia and supraventricular/ventricular arrhythmias, which may require a reduction in dosage. The concurrent use of β blockers is a common cause of blunted clinical responsiveness to dobutamine. It can be overcome by higher doses in case of bisoprolol and metoprolol, but not as easily for carvedilol, which has a very slow dissociation rate.

**Epinephrine**
The natural sympathetic agonist is mainly produced by the adrenal gland and systemically released. It is a balanced β1, β2, and α1-adrenergic agonist and has a similar net hemodynamic effect as dobutamine, but with a stronger tachycardic effect, which makes it a second-choice inotrope in acutely decompensated heart failure.

**Norepinephrine**
The main sympathetic neurotransmitter released from sympathetic nerve endings is a potent β1 and α1 agonist and weak β2 receptor agonist. This profile causes the positive inotropism accompanied by prominent vasoconstriction and increased afterload. Vasoconstriction of coronary blood vessels promotes ischemia; increased afterload may impede cardiac output (Figure 29–4). However, the stronger blood pressure-increasing effect of NE may be needed in persistent hypotension despite adequate cardiac filling pressures. Moreover, the increase in mean blood pressure leads to a reflex increase in parasympathetic nervous tone that can antagonize the direct tachycardic effect of NE and actually cause bradycardia.

**Dopamine**
The pharmacologic and hemodynamic effects of DA vary with concentration. Low doses (≤2 μg/kg lean body mass/min) induce cAMP-dependent vascular smooth muscle vasodilation by direct stimulation of D2 receptors. Activation of D2 receptors on sympathetic nerves in the peripheral circulation also inhibits NE release and reduces α1-adrenergic stimulation of vascular smooth muscle, particularly in splanchnic and renal arterial beds. This is the pharmacological basis for the “low-dose DA infusion” historically used to increase renal blood flow and maintain an adequate GFR and diuresis in hospitalized patients with CHF with impaired renal function refractory to diuretics. However, mainly negative clinical studies argue against the validity of this concept (Chen et al., 2013; Vargo et al., 1996). At intermediate infusion rates (2–5 μg/kg/min), dopamine directly stimulates cardiac β receptors to enhance myocardial contractility. At higher infusion rates (5–15 μg/kg/min), a β adrenergic receptor stimulation-mediated peripheral arterial and venous constriction occurs. The complex profile and negative clinical data on low-dose infusion make DA a second or third choice in the treatment of heart failure.

**Phosphodiesterase Inhibitors**
The cAMP-PDE inhibitors decrease cellular cAMP degradation, resulting in elevated levels of cAMP. This results in positive inotropic and chronotropic effects in the heart and dilation of resistance and capacitance vessels, effectively decreasing preload and afterload (thus the term inotrope). PDE inhibitors may be more advantageous than catecholamines in patients on β blockers and in patients with high systemic or pulmonary artery resistance. Hypotension is often dose limiting; tachycardic and arrhythmogenic effects are similar to those of catecholamines.

**Miloamine and Enoximone.** Parenteral formulations of milrinone and enoximone are used for short-term circulation support in advanced CHF. Enoximone (not available in the U.S.) is a relative selective inhibitor of PDE3, the cGMP-inhibited CAMP PDE and main isoform involved in inotropic control in human heart. Milrinone inhibits human heart PDE3 and PDE4 with similar potency (Bethke et al., 1992). By increasing intracellular CAMP concentrations, they have similar actions as the β receptor agonists dobutamine and EPI, but tend to lower systemic and pulmonary vascular resistance more than do the catecholamines. It should be kept in mind that PDE inhibitors potentiate the actions of β receptor agonists, both beneficial and detrimental. The loading dose of milrinone is ordinarily 25–75 μg/kg, and the continuous infusion rate ranges from 0.375 to 0.75 μg/kg/min. Bolus doses of enoximone at 0.5–1.0 mg/kg over 5–10 min are followed by an infusion of 5–20 μg/kg/min. The elimination half-lives of milrinone and enoximone in normal individuals are 0.5–1 h and 2–3 h, respectively, but can be increased in patients with severe CHF.

**Myofilament Calcium Sensitizers (Levosimendan, Pimobendan)**
In some countries but not in the U.S., calcium sensitizers are approved for the short-term treatment of acutely decompensated heart failure (e.g., levosimendan in Sweden, pimobendan in Japan). Calcium sensitizers increase the sensitivity of contractile myofilaments to Ca2+ by binding to and inducing a conformational change in the thin-filament regulatory protein troponin C. This causes an increased force for a given cytosolic Ca2+ concentration, theoretically without raising the [Ca2+]cytosol. However, a variety of other effects has been ascribed to pimobendan and levosimendan, including inhibition of PDEs, inhibition of the production of pro-inflammatory cytokines, and opening of ATP-dependent potassium channels. Clinical data provide evidence for symptomatic benefit and reductions in the length of stay in the hospital but do not support a better safety profile of levosimendan compared to catecholamines or classical PDE inhibitors (Mebazaa et al., 2007). In cases of hyperkalemia and death are likely related to the PDE3 inhibitor activity of these compounds.

**Other Drugs Used in Heart Failure**
The vasopressin receptor antagonist tolvaptan is FDA-approved for the treatment of therapy-resistant hyponatremia, a common and difficult-to-treat complication in decompensated heart failure. Studies in a more general cohort of patients with heart failure failure to show convincing beneficial effects of this compound. Severe thirst and dehydration are common side effects. Heparin or other anticoagulants are routinely used in hospitalized patients with heart failure to prevent thromboembolism.

**Role of Standard Combination Therapy**
The majority of patients hospitalized with acutely decompensated heart failure have preexisting heart failure and respective maintenance therapy. Guidelines suggest reviewing a patient’s existing therapy on admission to determine whether recent changes in the medication could be causally related to an exacerbation of cardiac disease. If not, the standard heart failure medication (ACEI, β-blocker, MRA, diuretic) should be continued in the absence of hemodynamic instability or contraindications (Yancy et al., 2013).

**Lessons From Heart Failure Drug Development**
Heart failure is an attractive but difficult indication for drug development. The number of drug development failures over the past two decades largely exceeded that of successes, indicating our incomplete understanding of the pathophysiology of heart failure, but sometimes also signaling problematic trial design. Even negative trials have helped to better understand the disease. Examples of drugs that have been tested in large prospective trials and failed are listed in Table 29–6.

**Lessons From Failed Drugs**
The failure of positive inotropic agents (PDE inhibitors, catecholamines, calcium sensitizers, mixed-acting compounds such as flosequinan or...
Trend toward increased mortality, no benefit.

The drugs currently recommended (furosemide, nitroglycerin, dobutamine) for the treatment of acutely decompensated heart failure have never been tested in adequately powered prospective clinical trials. All novel drugs tested either in comparison to standard inotropes or noninotropes or as an add-on have failed to show convincing superiority or benefit in terms of symptoms, duration of hospitalization, and 30-day mortality. The A1 adenosine receptor antagonist rolophylline should produce several beneficial effects on the kidney, including inhibition of tubular reabsorption of Na+ and water, dilation of the afferent arteriole, and inhibition of tubuloglomerular feedback, but its addition to standard therapy in patients with acute heart failure with impaired kidney function produced no salutary renal or cardiac effects and caused unacceptable adverse effects such as seizures, a typical side effect of central A1 adenosine antagonism known also from theophylline (Massie et al., 2010).

**Recent Developments; Novel Approaches**

Numerous pharmacological and nonpharmacological treatment options are being tested in preclinical and clinical studies (https://www.clinicaltrials.gov). They range from cell and gene therapies to food supplements (vitamins, polyunsaturated fatty acid) and intravenous iron to classical small molecules. In the CUPID2 trial, gene therapy, in the form of an intracoronary infusion of adeno-associated virus 1/SERCA2, did not provide any benefit in HFrEF (Chung et al., 2003; Mann et al., 2004).

Endothelin 1, a potent vasoconstructor, is upregulated in heart failure and could play an adverse role in heart failure, similar to that of AngII. Nonselective ET receptor antagonists such as bosentan had striking efficacy in postinfarct rodent models and are successfully used in pulmonary hypertension (Chapter 31). However, bosentan showed no efficacy in patients with chronic heart failure (Packer et al., 2005). Omapatrilat, a dual inhibitor of ACE and nphyrilysin, can decrease AngII and increase ANP/BNP; conditions promoting vasodilation, diuresis, and anti hypertrophic effects; however, expectations that omapatrilat would be more efficacious than an ACEI in heart failure were not confirmed in a prospective study (Packer et al., 2002).

Numerous clinical trials have tested the idea that adding an ARB or the renin inhibitor aliskiren to standard therapy that includes an ACEI would be beneficial by more completely inhibiting the RAAS. With the exception of one trial (McMurray et al., 2003), studies of these combinations consistently showed a lack of benefit and an increase in adverse effects, particularly decreased renal function and hyperkalemia. The premise was that if some inhibition of the RAAS is good, more would be better; perhaps the premise was wrong.

Statins were proposed to have anti-inflammatory, antihypertrophic, and pro-angiogenic effects independent of their cholesterol-lowering effect (Liao and Laufs, 2005). Trials testing this hypothesis by adding statins to standard treatment of chronic heart failure demonstrated that the combination was safe but had no added beneficial effect on mortality (Kjekshus et al., 2007). An antagonist of the V1 vasopressin receptor tolvaptan was ineffective in patients with chronic stable heart failure (Udelson et al., 2007). The discrepancy to several positive preclinical and early clinical studies suggests that the vasopressin axis of the neurohormonal activation program in heart failure may be sufficiently addressed by standard combination therapy, leaving no room for further improvement.

**Lessons From Treating Acute Heart Failure**

The drugs currently recommended (furosemide, nitroglycerin, dobutamine) for the treatment of acutely decompensated heart failure have never been tested in adequately powered prospective clinical trials. All novel drugs tested either in comparison to standard inotropes or noninotropes or as an add-on have failed to show convincing superiority or benefit in terms of symptoms, duration of hospitalization, and 30-day mortality. The A1 adenosine receptor antagonist rolophylline should produce several beneficial effects on the kidney, including inhibition of tubular reabsorption of Na+ and water, dilation of the afferent arteriole, and inhibition of tubuloglomerular feedback, but its addition to standard therapy in patients with acute heart failure with impaired kidney function produced no salutary renal or cardiac effects and caused unacceptable adverse effects such as seizures, a typical side effect of central A1 adenosine antagonism known also from theophylline (Massie et al., 2010).
sGC). Riociguat is a direct, heme-dependent stimulator of sGC; cinaciguat is a heme-independent activator of sGC. Oxidative inactivation of sGC is believed to be a common pathology in cardiovascular disease and a reason for endothelial dysfunction. sGC activators have maintained (or even enhanced) effects at sGC enzymes inactivated by oxidation. Riociguat is approved for the treatment of pulmonary artery hypertension and chronic thromboembolic pulmonary hypertension (see Chapter 31). A prospective study with cinaciguat was prematurely stopped because the drug not only lowered pulmonary wedge pressure and increased cardiac output, but also markedly increased the rate of symptomatic hypotension (Erdmann et al., 2013), a classical problem of vasodilator therapy in acute heart failure. Heart failure is often associated with anemia, a predictor of a poor prognosis. Yet, correction of anemia by an erythropoietin derivative, darbopoetin alpha, did not affect any clinical end point but increased the rate of thromboembolic events and ischemic strokes in patients with heart failure and mild-to-moderate anemia (Swedberg et al., 2013). However, intravenous iron, added to standard therapy in patients with NYHA class II–III heart failure, iron deficiency, and hemoglobin levels of 9.5–13.5 g/dL, improved quality of life, NYHA class, and physical exercise capacity (Anker et al., 2009). The beneficial effects seemed to be independent of the presence of anemia and may be related to other roles of iron in the body. Larger prospective studies are needed to confirm the effects.

Acknowledgment: Henry Ooi, Wilson Colucci, Bradley A. Maron, James C. Fang, and Thomas P. Rocco have contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.

</table>

Cardiac cells undergo depolarization and repolarization about 60 times per minute to form and propagate cardiac action potentials. The shape and duration of each action potential are determined by the activity of ion channel protein complexes in the membranes of individual cells, and the genes encoding most of these proteins and their regulators now have been identified. Action potentials in turn provide the primary signals to release Ca²⁺ from intracellular stores and to thereby initiate contraction. Thus, each normal heartbeat results from the highly integrated electrophysiological behavior of multiple proteins on the surface and within multiple cardiac cells. Disordered cardiac rhythm can arise from influences such as inherited variation in ion channel or other genes, ischemia, sympathetic stimulation, or myocardial scarring. Available antiarrhythmic drugs suppress arrhythmias by blocking flow through specific ion channels or by altering autonomic function. An increasingly sophisticated understanding of the molecular basis of normal and abnormal cardiac rhythm may lead to identification of new targets for antiarrhythmic drugs and perhaps improved therapies (Dobrev et al., 2012; Van Wagoner et al., 2015).

Arrhythmias can range from incidental, asymptomatic clinical findings to life-threatening abnormalities. Mechanisms underlying cardiac arrhythmias have been identified in cellular and animal experiments. For some human arrhythmias, precise mechanisms are known, and treatment can be targeted specifically to those mechanisms. In other cases, mechanisms can be only inferred, and the choice of drugs is based largely on results of prior experience. Antiarrhythmic drug therapy has two goals: termination of an ongoing arrhythmia or prevention of an arrhythmia. Unfortunately, antiarrhythmic drugs may not only help control arrhythmias but also can cause them, even during long-term therapy. Thus, prescribing antiarrhythmic drugs requires that precipitating factors be excluded or minimized, that a precise diagnosis of the type of arrhythmia (and its possible mechanisms) be made, that the prescriber has reason to believe that drug therapy will be beneficial, and that the risks of drug therapy can be minimized.

Principles of Cardiac Electrophysiology

The flow of ions across cell membranes generates the currents that make up cardiac action potentials. Factors that determine the magnitude of individual currents and their modulation by drugs include transmembrane potential, time since depolarization, or the presence of specific ligands. Further, because the function of many channels is time and voltage dependent, even a drug that targets a single ion channel may, by altering the trajectory of the action potential, alter the function of other channels. Most antiarrhythmic drugs affect more than one ion current, and many exert ancillary effects, such as modification of cardiac contractility or autonomic nervous system function. Thus, antiarrhythmic drugs usually exert multiple actions and can be beneficial or harmful in individual patients.

The Cardiac Cell at Rest: a K⁺-Permeable Membrane

Ions move across cell membranes in response to electrical and concentration gradients, not through the lipid bilayer but through specific ion channels or transporters. The normal cardiac cell at rest maintains a transmembrane potential approximately 80 to 90 mV negative to the exterior; this gradient is established by pumps, especially the Na⁺, K⁺-ATPase, and fixed anionic charges within cells. There are both an electrical and a
concentration gradient that would move Na\(^+\) ions into resting cells (Figure 30–1). However, Na\(^+\) channels, which allow Na\(^+\) to move along this gradient, are closed in the cardiac cell at rest, so Na\(^+\) does not enter normal resting cardiac cells. In contrast, a specific type of K\(^+\) channel remains open at negative resting potentials. Hence, K\(^+\) can move through these channels across the cell membrane at negative potentials in response to either electrical or concentration gradients (Figure 30–1). For each individual ion, there is an equilibrium potential $E_x$ at which there is no net driving force for the ion to move across the membrane. $E_x$ can be calculated using the Nernst equation:

$$E_x = -\frac{RT}{FZ_x} \ln\left(\frac{[x]_i}{[x]_o}\right)$$  \hspace{1cm} (30–1)

where $Z_x$ is the valence of the ion, $T$ is the absolute temperature, $R$ is the gas constant, $F$ is Faraday’s constant, $[x]_o$ is the extracellular concentration of the ion, and $[x]_i$ is the intracellular concentration. For typical values for K\(^+\), $[K]_o = 4 \text{ mM}$ and $[K]_i = 150 \text{ mM}$, the calculated K\(^+\) equilibrium potential $E_K$ is $-96 \text{ mV}$. There is thus no net force driving K\(^+\) ions into or out of a cell when the transmembrane potential is $-96 \text{ mV}$, which is close to the resting potential. If $[K]_i$ is elevated to 10 mM, as might occur in diseases such as renal failure or myocardial ischemia, the calculated $E_K$ rises to $-70 \text{ mV}$. In this situation, there is excellent agreement between changes in theoretical $E_K$ owing to changes in $[K]_i$ and the actual measured transmembrane potential, indicating that the normal cardiac cell at rest is permeable to K\(^+\) (because inward rectifier channels are open) and that $[K]_i$ is the major determinant of resting potential.

The Cardiac Action Potential

Transmembrane current through voltage-gated ion channels is the primary determinant of cardiac action potential morphology and duration. Channels are macromolecular complexes consisting of a pore-forming transmembrane structure (which may be a single protein, often termed an α subunit, or a subunit, or a multimer), as well as function-modifying β subunits and other accessory proteins. Common features of the pore-forming structure include a voltage-sensing domain, a selectivity filter, a conducting pore, and an inactivating particle (Figure 30–2; see also Figure 22–2). In response to changes in local transmembrane potential, ion channels undergo conformational changes, allowing for, or preventing, the flow of ions through the conducting pore along their electrochemical gradient, generally in time-, voltage-, or ligand-dependent fashion.

To initiate an action potential, a cardiac myocyte at rest is depolarized above a threshold potential, usually via gap junctions by a neighboring myocyte. On membrane depolarization, Na\(^+\) channel proteins change conformation from the “closed” (resting) state to the “open” (conducting) state (Figure 30–2), allowing up to $10^7$ Na\(^+\) ions/s to enter each cell and moving the transmembrane potential toward $E_{Na^+} (+65 \text{ mV})$. This surge of Na\(^+\) ions lasts only about a millisecond, after which the Na\(^+\) channel protein rapidly changes conformation from the open state to an “inactivated,” nonconducting state (Figure 30–2). The maximum upstroke slope of phase 0 ($dV/\, dt_{max}$ or $V_{max}$) of the action potential (Figure 30–3) is largely governed by

![Figure 30-1](image1.png)  \hspace{1cm} Figure 30–1 Electrical and chemical gradients for K\(^+\) and for Na\(^+\) in a resting cardiac cell. Inward rectifier K\(^+\) channels are open (left), allowing K\(^+\) ions to move across the membrane and the transmembrane potential to approach $E_K$. In contrast, Na\(^+\) does not enter the cell despite a large net driving force because Na\(^+\) channel proteins are in the closed conformation (right) in resting cells.

![Figure 30-2](image2.png)  \hspace{1cm} Figure 30–2 Voltage-dependent conformational changes determine current flow through Na\(^+\) channels. At hyperpolarized potentials, the channel is in a closed conformation, and no current can flow (left). As depolarization begins, the voltage sensor (indicated here as ++++) moves, thus altering channel conformation and opening the pore, allowing conduction (middle). As depolarization is maintained, an intracellular particle blocks current flow, making the channel nonconducting in this inactivated state (right).
Na\(^+\) current and is a major determinant of conduction velocity of a propagating action potential. Under normal conditions, Na\(^+\) channels, once inactivated, cannot reopen until they reassume the closed conformation. However, a small population of Na\(^+\) channels may continue to open during the action potential plateau in some cells (Figure 30–3), providing further inward current, often termed a “late” Na\(^+\) current. As the cell membrane repolarizes, the negative membrane potential moves Na\(^+\) channel proteins from inactivated to closed conformations, from which they are again available to open and depolarize the cell. The relationship between Na\(^+\) channel availability and transmembrane potential is an important determinant of conduction and refractoriness in many cells, as discussed in the material that follows.

The changes in transmembrane potential generated by the inward Na\(^+\) current produce, in turn, a series of openings (and in some cases inactivation) of other channels (Figure 30–3). For example, when a cell is depolarized by the Na\(^+\) current, “transient outward” \(I_{\text{K}}\) channels quickly change conformation to enter an open, or conducting, state; because the transmembrane potential at the end of phase 0 is positive to \(E_K\), the opening of transient outward channels results in an outward, or repolarizing, \(K^+\) current (termed \(I_{\text{Ko}}\), which contributes to the phase 1 “notch” seen in some action potentials (e.g., more prominent in epicardium than in endocardium). Transient outward \(K^+\) channels, like Na\(^+\) channels, inactivate rapidly. During the phase 2 plateau of a normal cardiac action potential, inward, depolarizing currents, primarily through L-type Ca\(^{2+}\) channels, are balanced by outward, repolarizing currents primarily through \(K^+\) (“delayed rectifier”) channels. Delayed rectifier currents (collectively termed \(I_{\text{Ks}}\)) increase with time, whereas Ca\(^{2+}\) currents inactivate (and so decrease with time); as a result, cardiac cells repolarize (phase 3) several hundred milliseconds after the initial Na\(^+\) channel opening.

```
Figure 30–3  The relationship between an action potential from the conducting system and the time course of the currents that generate it. The current magnitudes are not to scale; the Na\(^+\) current is ordinarily 50 times larger than any other current, although the portion that persists into the plateau (phase 2) is small. Multiple types of Ca\(^{2+}\) current, transient outward current \(I_{\text{To}}\), and delayed rectifier \(I_{\text{Ks}}\) have been identified. Each represents a different channel protein, usually associated with ancillary (function-modifying) subunits. 4-AP is a widely used in vitro blocker of K+ (“delayed rectifier”) channels. Delayed rectifier currents (collectively termed \(I_{\text{Ks}}\)) increase with time, whereas Ca\(^{2+}\) currents inactivate (and so decrease with time); as a result, cardiac cells repolarize (phase 3) several hundred milliseconds after the initial Na\(^+\) channel opening.
```

A common mechanism whereby drugs prolong cardiac action potentials and provoke arrhythmias is inhibition of a specific delayed rectifier current, \(I_{\text{Ks}}\), generated by expression of KCNH2 (formerly termed the HERG). The ion channel protein generated by KCNH2 expression differs from other ion channels in important structural features that make it much more susceptible to drug block; understanding these structural constraints is an important first step to designing drugs lacking \(I_{\text{Ks}}\)-blocking properties (Mitcheson et al., 2000). Avoiding \(I_{\text{Ks}}/\text{KCNH2}\) channel block has become a major issue in drug development (Rodent, 2004).

**Maintenance of Intracellular Ion Homeostasis**

With each action potential, the cell interior gains Na\(^+\) ions and loses K\(^+\) ions. An ATP-requiring Na\(^+\)–K\(^+\) exchange mechanism, or pump, is activated in most cells to maintain intracellular homeostasis. This Na\(^+\), K\(^+\)-ATPase extrudes three Na\(^+\) ions for every two K\(^+\) ions shuttled from the exterior of the cell to the interior; as a result, the act of pumping itself is electrogenic, generating a net outward (repolarizing) current.

Normally, intracellular Ca\(^{2+}\) is maintained at very low levels (<100 nM). In cardiac myocytes, the entry of Ca\(^{2+}\) during each action potential through L-type Ca\(^{2+}\) channels is a signal to the SR to release its Ca\(^{2+}\) stores, and thus initiate Ca\(^{2+}\)-dependent contraction, a process termed excitation-contraction coupling. The efflux of Ca\(^{2+}\) from the SR occurs through ryanodine receptor release channels (RyR2) and subsequent removal of intracellular Ca\(^{2+}\) occurs by both SERCA2, which moves Ca\(^{2+}\) ions back into the SR, and an electrogenic NCX on the cell surface, which exchanges three Na\(^+\) ions from the exterior for every Ca\(^{2+}\) ion extruded.

**Genetic Arrhythmia Diseases**

Rare congenital arrhythmia diseases such as the LQTS and CPVT can cause sudden death due to fatal arrhythmias, often in young subjects. The identification of disease genes not only has resulted in improved care of affected patients and their families but also has contributed importantly to our understanding of the normal action potential, arrhythmia mechanisms, and potential antiarrhythmic drug targets (Keating and Sanguinetti, 2001). For example, mutations in the cardiac Na\(^+\) channel gene SCN5A can cause one form of LQTS by destabilizing fast inactivation, increasing late Na\(^+\) current, thereby prolonging action potentials, and thus the QT interval (as discussed in material that follows). Drugs inhibiting this abnormal current may be antiarrhythmic in this form of LQTS (Remme and Wilde, 2013), and drugs increasing late Na\(^+\) current may cause arrhythmias (Yang et al., 2014). Inhibitors may include not only antiarrhythmics such as mexiletine or flecainide discussed in this chapter, but also the antianginal agent ranolazine (see Chapter 28), which appears to be a late Na\(^+\) current blocker.

Similarly, mutations in the RyR2 gene encoding an intracellular Ca\(^{2+}\) release channel (or less commonly in other genes regulating RyR2 function) cause CPVT by generating “leaky” RyR2 channels, perturbing intracellular Ca\(^{2+}\) homeostasis and causing DAD-dependent arrhythmias described further in this chapter. Drugs such as flecainide and propafenone that inhibit these abnormal RyR2 channels appear to prevent CPVT in mouse models and in humans (Watanabe et al., 2009). Intriguingly, some arrhythmias in acquired heart disease have been attributed to increased late Na\(^+\) current or leaky RyR2 channels. Thus, studies in the rare congenital arrhythmia syndromes may point to new avenues for drug development in more common arrhythmias in acquired heart disease (Knollmann and Roden, 2008 Priori et al., 1999).

**Action Potential Heterogeneity in the Heart**

The general description of the action potential and the currents that underlie it must be modified for certain cell types (Figure 30–4), primarily due to variability in the expression of ion channels and electrogenic ion transport pumps. The resultant diversity of action potentials in different regions of the heart plays a role in understanding the pharmacological profiles of antiarrhythmic drugs. In the ventricle, action potential duration varies across the wall of each chamber, as well as apicobasally, largely as a consequence of varying densities of repolarizing currents. In the
neighboring His-Purkinje conduction system, action potentials are longer, probably due to decreased K⁺ currents, increased “late” Na⁺ currents, and differences in intercellular Ca²⁺ handling (Dun and Boyden, 2008).

Atrial cells have shorter action potentials than ventricular cells because of larger early repolarization currents such as I_{TO}. Atrial cells also express an additional repolarizing K⁺ channel that is activated by the neurotransmitter acetylcholine and accounts for action potential shortening with vagal stimulation. Cells of the sinus and AV nodes lack substantial Na⁺ currents, and depolarization is achieved by inward current generated by opening of Ca²⁺ channels. In addition, these cells, as well as cells from the conducting system, normally display the phenomenon of spontaneous diastolic, or phase 4, depolarization and thus spontaneously reach threshold for regeneration of action potentials. The rate of spontaneous firing usually is fastest in sinus node cells, which therefore serve as the natural pacemaker of the heart. The slow diastolic depolarization that underlies pacemaker activity is generated by a nonselective channel that conducts both Na⁺ and K⁺ and is activated at hyperpolarized membrane potentials (Cohen and Robinson, 2006). In diseased cells, pacemaker-like activity can arise from spontaneous Ca²⁺ release from the SR, followed by membrane depolarization due to activation of NCX.

Certain ion channels are expressed only in some tissues or become active only under specific pathophysiological conditions. For example, the T-type Ca²⁺ channel may be important in diseases such as hypertension and play a role in pacemaker activity (Ono and Iijima, 2010). A T-type-selective Ca²⁺ channel antagonist, mibebradil, was commercially available briefly in the late 1990s but was withdrawn because of concerns over potentially life-threatening pharmacokinetic interactions with many other drugs. A second example is a channel that transports Cl⁻ ions and results in repolarizing currents (I_{Cl}) (Duan, 2013); some of these are observed only in association with pathophysiological conditions. A third example is the K⁺ channel that are quiescent when intracellular ATP stores are normal and become active when these stores are depleted. Such ATP-inhibited K⁺ channel may become particularly important in repolarizing cells during states of metabolic stress such as myocardial ischemia (Tamargo et al., 2004).

### Impulse Propagation and the Electrocardiogram

Normal cardiac impulses originate in the sinus node. Impulse propagation in the heart depends on the magnitude of the depolarizing current (usually Na⁺ current) and the geometry and density of cell–cell electrical connections (Kleber and Saffitz, 2014). Cardiac cells are relatively long and thin and well coupled through specialized gap junction proteins at their ends, whereas lateral (“transverse”) gap junctions are sparser. As a result, impulses spread along cells two to three times faster than across cells. This “anisotropic” (direction-dependent) conduction may be a factor in the genesis of certain arrhythmias described in the material that follows (Priori et al., 1999).

Once impulses leave the sinus node, they propagate rapidly throughout the atria, resulting in atrial systole and the P wave of the surface ECG (Figure 30–4). Propagation slows markedly through the AV node, where the inward current (through Ca²⁺ channels) is much smaller than the Na⁺ current in atria, ventricles, or the subendocardial conducting system. This conduction delay, represented as the PR interval on the ECG, allows the atrial contraction to propel blood into the ventricle, thereby optimizing cardiac output.

Once impulses exit the AV node, they enter the conducting system, where Na⁺ currents are larger than in any other tissue, and propagation is correspondingly faster, up to 0.75 m/s longitudinally. Activation spreads from the His-Purkinje system on the endocardium of the ventricles throughout the rest of the ventricles, stimulating coordinated ventricular contraction. This electrical activation manifests itself as the QRS complex on the ECG. Ventricular repolarization is presented on the surface ECG as the T wave. The time from initial depolarization in the ventricle until the end of repolarization is termed the QT interval. Lengthening of ventricular action potentials prolongs the QT interval and may be associated with arrhythmias in LQTS and other settings.

### Refractoriness and Conduction Failure

In atrial, ventricular, and His-Purkinje cells, if a restimulation occurs very early during the plateau of an action potential, no Na⁺ channels are
available to open, so no inward current results, and no new action potential is generated: At this point, the cell is termed refractory (Figure 30–5). On the other hand, if a stimulus occurs after the cell has repolarized completely, Na+ channels have recovered from inactivation, and a normal Na+ channel–dependent upstroke results with the same amplitude as the previous upstroke (Figure 30–5A). When a stimulus occurs during phase 3 of the action potential, the upstroke of the premature action potential is slower and of smaller magnitude. The magnitude depends on the number of Na+ channels that have recovered from inactivation (Figure 30–5A), which in turn is dependent on the membrane potential. Thus, refractoriness is determined by the voltage-dependent recovery of Na+ channels from inactivation.

Refractoriness frequently is measured by assessing whether premature stimuli applied to tissue preparations (or the whole heart) result in propagated impulses. While the magnitude of the Na+ current is one major determinant of propagation of premature beats, cellular geometry also is important in multicellular preparations. Propagation from cell to cell requires current flow from the first site of activation and consequently can fail if inward current is insufficient to drive activation in many neighboring cells. The ERP is the longest interval at which a premature stimulus fails to generate a propagated response and often is used to describe drug effects in intact tissue.

The situation is different in tissue whose depolarization is largely controlled by Ca2+ channel current, such as the AV node. Because Ca2+ channels have a slower recovery from inactivation, these tissues are often referred to as slow response (Figure 30–5C), in contrast to fast response in the remaining cardiac tissues. Even after a Ca2+ channel–dependent action potential has repolarized to its initial resting potential, not all Ca2+ channels are available for reexcitation. Therefore, an extra stimulus applied shortly after repolarization is complete generates a reduced Ca2+ current, which may propagate slowly to adjacent cells prior to extinction. An extra stimulus applied later will result in a larger Ca2+ current and faster propagation. Thus, in Ca2+ channel–dependent tissues, which include not only the AV node but also tissues whose underlying characteristics have been altered by factors such as myocardial ischemia, refractoriness is prolonged, and propagation occurs slowly. Conduction that exhibits such dependence on the timing of premature stimuli is termed decremental. Slow conduction in the heart, a critical factor in the genesis of reentrant arrhythmias (see further discussion), also can occur when Na+ currents are depressed by disease or membrane depolarization (e.g., elevated [K+]), resulting in decreased steady-state Na+ channel availability (Figure 30–5B).

**Mechanisms of Cardiac Arrhythmias**

An arrhythmia is by definition a perturbation of the normal sequence of impulse initiation and propagation. Failure of impulse initiation, in the sinus node, may result in slow heart rates (bradyarrhythmias), whereas failure in the normal propagation of action potentials from atrium to ventricle results in dropped beats (commonly referred to as heart block) and usually reflects an abnormality in either the AV node or the His-Purkinje system. These abnormalities may be caused by drugs (Table 30–1) or by structural heart disease; in the latter case, permanent cardiac pacing may be required.

Abnormally rapid heart rhythms (tachyarrhythmias) are common clinical problems that may be treated with antiarrhythmic drugs. Three major underlying mechanisms have been identified: enhanced automaticity, triggered automaticity, and reentry. These are often interrelated mechanisms as abnormal beats arising from one mechanism can elicit a second; for example, a triggered automatic beat can initiate reentry.

**Enhanced Automaticity**

Enhanced automaticity may occur in cells that normally display spontaneous diastolic depolarization—the sinus and AV nodes and the His-Purkinje system. β Adrenergic stimulation, hypokalemia, and mechanical stretch of cardiac muscle cells increase phase 4 slope and so accelerate pacemaker rate, whereas acetoholamine reduces pacemaker rate both by decreasing phase 4 slope and by hyperpolarization (making the maximum diastolic potential more negative). In addition, automatic behavior may occur in sites that ordinarily lack spontaneous pacemaker activity; for example, depolarization of ventricular cells (e.g., by ischemia) may produce “abnormal” automaticity. When impulses propagate from a region of enhanced normal or abnormal automaticity to excite the rest of the heart, more complex arrhythmias may result from the induction of reentry.

**Afterdepolarizations and Triggered Automaticity**

Under some pathophysiological conditions, a normal cardiac action potential may be interrupted or followed by an abnormal depolarization (Figure 30–6). If this abnormal depolarization reaches threshold, it may, in turn, give rise to secondary upstrokes that can propagate and create abnormal rhythms. These abnormal secondary upstrokes occur only after an initial normal, or “triggering,” upstroke and thus are termed triggered rhythms.

Two major forms of triggered rhythms are recognized. In the first case, under conditions of intracellular or SR Ca2+ overload (e.g., myocardial ischemia, adrenergic stress, digitalis intoxication, or CPVT), a normal action potential may be followed by a DAD (Figure 30–6A); as discussed previously, enhanced NCX current is thought to be a common mechanism underlying DADs. If this afterdepolarization reaches threshold, a secondary triggered beat or beats may occur. DAD amplitude is increased in vitro by rapid pacing, and clinical arrhythmias thought to correspond to DAD-mediated triggered beats are more frequent when the underlying cardiac rate is rapid (Priori et al., 1999).

In the second type of triggered activity, the key abnormality is marked prolongation of the cardiac action potential. When this occurs, phase 3 repolarization may be interrupted by an EAD (Figure 30–6B). EAD-mediated triggering in vitro and clinical arrhythmias are most common when the
### CHAPTER 30

### ANTIARRHYTHMIC DRUGS

Reentry occurs when a cardiac impulse travels in a path such as to return to its original site and reactivate the original site, thus perpetuating rapid reactivation independent of normal sinus node function. Key features enabling reentrant excitation are a pathway; heterogeneity of electrophysiologic properties, notably refractoriness, along the pathway; and slow conduction.

**Anatomically Defined Reentry**

The prototypical example of reentry is the WPW syndrome in which patients have an accessory connection between the atrium and ventricle (Figure 30–7). With each sinus node depolarization, impulses can excite the ventricle via the normal structures (AV node) or the accessory pathway, and this often results in an unusual and characteristic QRS complex in normal sinus rhythm. Importantly, the electrophysiological properties of the AV node and accessory pathways are different: Accessory pathways usually consist of nonnodal tissue with longer refractory periods and without decremental conduction. Thus, with a premature atrial beat (e.g., from abnormal automaticity), conduction may fail in the accessory pathway but continue, albeit slowly, in the AV node and then through the His-Purkinje system; there the propagating impulse may encounter the ventricular end of the accessory pathway when it is no longer refractory. The likelihood

underlying heart rate is slow, extracellular K⁺ is low, and certain drugs that prolong action potential duration (antiarrhythmics and others) are present. EAD-related triggered upstrokes probably reflect inward current through Na⁺ or Ca²⁺ channels. Due to their intrinsically longer action potential durations across the ventricular wall (Priori et al., 1999). Congenital LQTS, a disease in which torsades de pointes causes syncope or death, is most often caused by mutations in the genes encoding the Na⁺ channels (10%) or the channels underlying the repolarizing currents I_kr and I_max (80-90%) (Nerbonne and Kass, 2005).
While antiarrhythmic drugs or electrical cardioversion are used to terminate reentry acutely (discussed further in the chapter and Table 30–2), the primary therapy for anatomically defined reentry is radio-frequency ablation because its consistent pathway often makes it possible to identify and ablate critical segments of this pathway effectively, curing the patient and obviating the need for long-term drug therapy. Radio-frequency ablation is carried out through a catheter advanced to the interior of the heart and requires minimal convalescence.

**Functionally Defined Reentry**

Reentry also may occur in the absence of a distinct, anatomically defined pathway (Figure 30–8). For example, a premature beat from within the ventricular wall may encounter refractory tissue in only one direction, allowing for conduction throughout the rest of the wall until the originally refractory area recovers, reexcites, and then propagates back through the original location of the premature beat. Another example is localized ischemia or other electrophysiological perturbations that result in an area of sufficiently slow conduction in the ventricle that impulses exiting from that area find the rest of the myocardium reexcitable, in which case reentry may ensue. Atrial fibrillation and VF are extreme examples of “functionally defined” reentry: Cells are reexcited as soon as they are repolarized sufficiently to allow enough Na+ channels to recover from inactivation. The abnormal activation pathway subsequently provides abnormal spatial heterogeneity of repolarization that can cause other reentrant circuits to form. In atrial fibrillation, these can persist for years, and rotor-like activity can sometimes be recorded, presumably reflecting reentrant circuits that can be transiently stable or meander around the atrium.

**Common Arrhythmias and Their Mechanisms**

The primary tool for diagnosis of arrhythmias is the ECG. More sophisticated approaches sometimes are used, such as recording from specific regions of the heart during artificial induction of arrhythmias by specialized pacing techniques. Table 30–2 lists common arrhythmias, their likely mechanisms, and approaches that should be considered for their acute termination and for long-term therapy to prevent recurrence. Examples of some arrhythmias discussed here are shown in Figure 30–9. Some arrhythmias, notably VF, are treated not pharmacologically but with DC cardioversion—the application of a large electric current across the chest. This technique also can be used to immediately restore normal rhythm in less-serious cases; if the patient is conscious, a brief period of general anesthesia is required. ICDs, devices that are capable of detecting VF and automatically delivering a defibrillating shock, are used increasingly in patients judged to be at high risk for VF. Often, drugs are used with these devices if defibrillating shocks, which are painful, occur frequently.

**Mechanisms of Antiarrhythmic Drug Action**

Antiarrhythmic drugs almost invariably have multiple effects in patients, and their effects on arrhythmias can be complex. A drug can modulate other targets in addition to its primary site of action. At the same time, a single arrhythmia may result from multiple underlying mechanisms (e.g., torsades de pointes [Figure 30–9H] can result either from increased Na+ channel late currents or decreased inward rectifier currents). Thus, antiarrhythmic therapy should be tailored to target the most relevant underlying arrhythmia mechanism, where it is known. Drugs may be antiarrhythmic by suppressing the initiating mechanism or by altering reentrant circuits. In some cases, drugs may suppress an initiator but nonetheless promote reentry (see discussion that follows).

Drugs may slow automatic rhythms by altering any of the four determinants of spontaneous pacemaker discharge (Figure 30–10): (1) increase maximum diastolic potential, (2) decrease phase 4 slope, (3) increase threshold potential, or (4) increase action potential duration. Adenosine and acetylcholine may increase maximum diastolic potential, and β blockers (see Chapter 12) may decrease phase 4 slope. Blockade of Na+ or Ca2+ channels usually results in altered threshold, and blockade of cardiac K+ channels prolongs the action potential.
Antiarrhythmic drugs may suppress arrhythmias owing to DADs or EADs by two major mechanisms:

1. inhibition of the development of afterdepolarizations; and
2. interference with the inward current (usually through Na⁺ or Ca²⁺ channels), which is responsible for the upstroke.

Thus, arrhythmias owing to DADs (i.e., due to digitalis toxicity or CPVT) may be inhibited by verapamil (which blocks the development of DAD by reducing Ca²⁺ influx into the cell, thereby decreasing SR Ca²⁺ load and the likelihood of spontaneous Ca²⁺ release from the SR) or by Na⁺ channel-blocking drugs, which elevate the threshold required to produce the abnormal upstroke. In CPVT, more effective than channel–blocking drugs, which elevate the threshold required to produce the abnormal upstroke. In CPVT, more effective than channel–blocking drugs, which elevate the threshold required to produce the abnormal upstroke. Atrial flutter

*Indicates treatment of choice. ‘Acute drug therapy is administered intravenously; chronic therapy implies long-term oral use. ‘AV nodal block can be achieved clinically by adenosine, Ca²⁺ channel blocker, β adrenergic receptor blockade, or increased vagal tone (a major antiarrhythmic effect of digitalis glycosides). ‘Ablation is a procedure in which tissue responsible for the maintenance of a tachycardia is identified by specialized recording techniques and then selectively destroyed, usually by high-frequency radio waves delivered through a catheter placed in the heart. ‘ICD, implanted cardioverter–defibrillator: a device that can sense VT or VF and deliver pacing and/or cardioverting shocks to restore normal rhythm. ‘These may be harmful in reentrant VT and so should be used for acute therapy only if the diagnosis is secure.

Accelerated by isoproterenol infusion or by pacing. Triggered beats arising from EADs can be inhibited by Mg²⁺ without normalizing repolarization in vitro or QT interval through mechanisms that are not well understood. In most forms of congenital LQTS, torsades de pointes occurs with adrenergic stress; therapy includes β adrenergic blockade (which does not shorten the QT interval but may prevent EADs) as well as pacing to shorten action potentials.

In anatomic determinations, drugs may terminate the arrhythmia by blocking propagation of the action potential. Conduction usually fails in a “weak link” in the circuit. In the example of the WPW-related arrhythmias described previously, the weak link is the AV node, and drugs that prolong AV nodal refractoriness and slow AV nodal conduction, such as Ca²⁺ channel blockers, β blockers, or adenosine, are likely to be effective. On the other hand, slowing conduction in functionally determined reentrant circuits may change the pathway without extinguishing the circuit. In fact, slow conduction generally promotes the development of reentrant circuits. Of particular note are β-adrenergic agents, which lengthen the QT interval and may thereby promote the development of contractile reentry.
interventions could thus be antiarrhythmic by preventing these changes (Van Wagoner et al., 2015).

**State-Dependent Ion Channel Block**

Knowing the structural and molecular determinants of ion channel permeation and drug block has provided key information for analyzing the actions of available and new antiarrhythmic compounds (MacKinnon, 2003). A key concept is that ion channel–blocking drugs bind to specific sites on the ion channel proteins to modify function (e.g., decrease current). The affinity of the ion channel protein for the drug on its target site generally varies as the ion channel protein shuttles among functional conformations (or ion channel “states”; see Figure 30–2). Physicochemical characteristics, such as molecular weight and lipid solubility, are important determinants of this state-dependent binding. State-dependent binding has been studied most extensively in the case of Na⁺ channel–blocking drugs. Most useful agents of this type block open or inactivated Na⁺ channels and have little affinity for channels in the resting state. Most Na⁺ channel blockers bind to a local anesthetic binding site in the pore of Na⁺ channels (Fozzard et al., 2005). Thus, during each action potential, drugs bind to Na⁺ channels and block them, and with each diastolic interval, drugs dissociate, and the block is released. Allosteric mechanisms have also been described whereby drug binding to a site distant from the pore nevertheless alters channel conformation and thus permeation though the pore.

As illustrated in Figure 30–12, the dissociation rate is a key determinant of steady-state block of Na⁺ channels. When heart rate increases, the time available for dissociation decreases, and steady-state Na⁺ channel block increases. The rate of recovery from block also slows as cells are depolarized, as in ischemia. This explains the finding that Na⁺ channel blockers depress Na⁺ current, and hence conduction, to a greater extent in ischemic tissues than in normal tissues. Open- versus inactivated-state block also may be important in determining the effects of some drugs. Increased action potential duration, which results in a relative increase in time spent in the inactivated state, may increase block by drugs that bind to inactivated channels, such as lidocaine or amiodarone.

The rate of recovery from block often is expressed as a time constant (τ_recovery, the time required to complete approximately 63% of an exponentially determined process to be complete). In the case of drugs such as lidocaine, τ_recovery is so short (<1 sec) that recovery from block is very rapid, and substantial Na⁺ channel block occurs only in rapidly driven tissues, particularly in ischemia. Conversely, drugs such as flecainide have such long τ_recovery values (>10 sec) that roughly the same numbers of Na⁺ channels are blocked during systole and diastole. As a result, slowing of conduction occurs even in normal tissues at normal rates.

**Classifying Antiarrhythmic Drugs**

Classifying drugs by common electrophysiological properties emphasizes the connection between basic electrophysiological actions and antiarrhythmic effects (Vaughan Williams, 1992). To the extent that the clinical actions of drugs can be predicted from their basic electrophysiological properties, such classification schemes have merit. However, as each compound is better characterized in a range of in vitro and in vivo test systems, it becomes apparent that differences in pharmacological effects occur even among drugs that share the same classification, some of which may be responsible for the observed clinical differences in responses to drugs of the same broad “class” (Table 30–3).

An alternative way of approaching antiarrhythmic therapy is to attempt to classify arrhythmia mechanisms and then to target drug therapy to the electrophysiological mechanism most likely to terminate or prevent the arrhythmia (Priori et al., 1999; Task Force, 1991) (Table 30–2). This approach has been further enhanced by an increasing understanding of arrhythmia mechanisms in genetic diseases such as LQTS and CPVT, so a genetic framework represents a complementary approach for improving antiarrhythmic drug development and therapy (Knollmann and Roden, 2008).
**Na⁺ Channel Block**

The extent of Na⁺ channel block depends critically on heart rate and membrane potential, as well as on drug-specific physicochemical characteristics that determine \( t_{\text{recovery}} \) (Figure 30–12). The description that follows applies when Na⁺ channels are blocked, that is, at rapid heart rates in diseased tissue with a rapid-recovery drug such as lidocaine or even at normal rates in normal tissues with a slow-recovery drug such as flecainide. When Na⁺ channels are blocked, threshold for excitability is decreased; that is, greater membrane depolarization is required to open enough Na⁺ channels to overcome K⁺ currents at the resting membrane potential and elicit an action potential. This change in threshold probably contributes to the clinical finding that Na⁺ channel blockers tend to increase both pacing threshold and the energy required to defibrillate the fibrillating heart. These deleterious effects may be important if antiarrhythmic drugs are used in patients with pacemakers or implanted defibrillators. Na⁺ channel block decreases conduction velocity in nonnodal tissue and increases QRS duration. Usual doses of flecainide prolong QRS intervals by 25% or more during normal rhythm, whereas lidocaine increases QRS intervals only at very fast heart rates. Drugs with \( t_{\text{recovery}} \) values greater than 10 sec (e.g., flecainide) also tend to prolong the PR interval; it is not known whether this represents additional Ca²⁺ channel block (see discussion that follows) or block of fast-response tissue in the region of the AV node. Drug effects on the PR interval also are highly modified by autonomic effects. For example, quinidine actually tends to shorten the PR interval largely as a result of its vagolytic properties. Action potential duration is either unaffected or is shortened by Na⁺ channel block; some Na⁺ channel–blocking drugs do prolong cardiac action potentials but by other mechanisms, usually K⁺ channel block (Table 30–3).

By increasing threshold, Na⁺ channel block decreases automaticity (Figure 30–10B) and can inhibit triggered activity arising from DADs or EADs. Many Na⁺ channel blockers also decrease phase 4 slope (Figure 30–10A). In anatomically defined reentry, Na⁺ channel blockers may decrease conduction sufficiently to extinguish the propagating reentrant wavefront. However, as described previously, conduction slowing owing to Na⁺ channel block may exacerbate reentry. Block of Na⁺ channels also shifts the voltage dependence of recovery from inactivation (Figure 30–5B) to more negative potentials, thereby tending to increase refractoriness. Thus, whether a given drug exacerbates or suppresses reentrant arrhythmias depends on the balance between its effects on refractoriness and on conduction in a particular reentrant circuit. Lidocaine and mexiletine have short \( t_{\text{recovery}} \) values and are not useful in atrial fibrillation or flutter, whereas quinidine, flecainide, propafenone, and similar agents are effective in some patients. Many of these agents owe part of their antiarrhythmic activity to blockade of K⁺ channels.

**Na⁺ Channel Blocker Toxicity**

Conduction slowing in potential reentrant circuits can account for toxicity of drugs that block the Na⁺ channel (Table 30–1). For example, Na⁺ channel block decreases conduction velocity and hence slows atrial flutter rate. Normal AV nodal function permits a greater number of impulses to penetrate the ventricle, and heart rate actually may increase (Figure 30–9). Thus, with Na⁺ channel blocker therapy, atrial flutter rate may drop from 300 per min, with 2:1 or 4:1 AV conduction (i.e., a heart rate of 150 or 75 beats per min), to 220 per min, but with 1:1 transmission to the ventricle (i.e., a heart rate of 220 beats per min), with potentially disastrous consequences. This form of drug-induced arrhythmia is especially common during treatment with quinidine because the drug also increases AV nodal conduction through its vagolytic properties; flecainide, propafenone, and occasionally amiodarone also have been implicated. Therapy with Na⁺ channel blockers in patients with reentrant tachycardia after a myocardial infarction can increase the frequency and severity of arrhythmic episodes. Although the mechanism is unclear, slowed conduction allows the reentrant wavefront to persist within the tachycardia circuit. Such drug-exacerbated arrhythmia can be difficult to

---

**Figure 30–9** Electrocardiograms showing normal and abnormal cardiac rhythms. The P, QRS, and T waves in normal sinus rhythm are shown in panel A. Panel B shows a premature beat arising in the ventricle (arrow). PSVT is shown in panel C; this is most likely reentry using an accessory pathway (see Figure 30–7) or reentry within or near the AV node. In atrial fibrillation (panel D), there are no P waves, and the QRS complexes occur irregularly (and at a slow rate in this example); electrical activity between QRS complexes shows small undulations (arrow) corresponding to fibrillatory activity in the atria. In atrial flutter (panel E), the atria beat rapidly, approximately 250 beats/min (arrows) in this example, and the ventricular rate is variable. If a drug that slows the rate of atrial flutter is administered, 1:1 AV conduction (panel F) may occur. In monomorphic VT (panel G), identical wide QRS complexes occur at a regular rate, 180 beats per min. The electrocardiographic features of the torsades de pointes syndrome (panel H) include a very long QT interval (>600 ms in this example, arrow) and VT in which each successive beat has a different morphology (polymorphic VT). Panel I shows the disorganized electrical activity characteristic of VF.
MODULATION OF PULMONARY, RENAL, AND CARDIOVASCULAR FUNCTION

Figure 30–12  Recovery from block of Na⁺ channels during diastole. This recovery is the critical factor determining extent of steady-state Na⁺ channel block. Na⁺ channel blockers bind to (and block) Na⁺ channels in the open or inactivated states, resulting in phasic changes in the extent of block during the action potential. As shown in the middle panel, a decrease in the rate of recovery from block increases the extent of block. Different drugs have different rates of recovery, and depolarization reduces the rate of recovery. The right panel shows that increasing heart rate, which results in relatively less time spent in the rest state and also increases the extent of block. (Reproduced with permission from Roden DM, et al. Clinical pharmacology of antiarrhythmic agents. In: Josephson ME, ed. Sudden Cardiac Death. Blackwell Scientific, London, 1993, 182–185.)

Figure 30–11  Two ways to increase refractoriness. In this figure, the black dot indicates the point at which a sufficient number of Na⁺ channels (an arbitrary 25%; see Figure 30–5B) have recovered from inactivation to allow a premature stimulus to produce a propagated response in the absence of a drug. Block of Na⁺ channels (A) shifts voltage dependence of recovery (see Figure 30–5B) and so delays the point at which 25% of channels have recovered (red diamond), prolonging the ERP. Note that if the drug also dissociates slowly from the channel (see Figure 30–12), refractoriness in fast-response tissues actually can extend beyond full repolarization (“postrepolarization refractoriness”). Drugs that prolong the action potential (B) also will extend the point at which an arbitrary percentage of Na⁺ channels have recovered from inactivation, even without directly interacting with Na⁺ channels.

Figure 30–10  Four ways to reduce the rate of spontaneous discharge. The horizontal lines in panels B and C mark the threshold potentials for triggering an action potential before and after drug application.

Indicates an effect that is important in mediating the clinical action of a drug. \( \checkmark \)Indicates a demonstrable effect whose relationship to drug action in patients is less well established. Indicates drugs prescribed as racemates, and the enantiomers are thought to exert similar electrophysiologic effects. \( \checkmark \)Indicates racemates for which clinically relevant differences in the electrophysiologic properties of individual enantiomers have been reported (see text).

Drugs are listed here according to this scheme. It is important to bear in mind, however, that many drugs exert multiple effects that contribute to their clinical actions. It is occasionally clinically useful to subclassify Na+ channel blockers by their rates of recovery from drug-induced block (\( \tau_{\text{recovery}} \)) under physiologic conditions. Because this is a continuous variable and can be modulated by factors such as depolarization of the resting potential, these distinctions can become blurred. Class Ia, \( \tau_{\text{recovery}} \)< 1 s; class Ib, \( \tau_{\text{recovery}} \) 1–10 s; class Ic, \( \tau_{\text{recovery}} \)> 10 s. These class and subclass effects are associated with distinctive ECG changes, characteristic "class" toxicities, and efficacy in specific arrhythmia syndromes (see text).

### Action Potential Prolongation

Most drugs that prolong the action potential do so by blocking \( I_{\text{Na}} \) (Roden et al., 1993), although increased late Na+ current also produces this effect (Lu et al., 2012; Yang et al., 2014). Both drug effects increase action potential duration and reduce normal automaticity (Figure 30–10D). Increased action potential duration, seen as an increase in QT interval, increases refractoriness (Figure 30–11) and therefore should be an effective way of treating reentry (Task Force, 1991). Experimentally, K+ channel block produces a series of desirable effects: reduced defibrillation energy requirement, inhibition of VF owing to acute ischemia, and increased contractility (Roden, 1993; Singh, 1993). As shown in Table 30–3, many K+ channel–blocking drugs also interact with β adrenergic receptors (sotalol) or other channels (e.g., amiodarone and quinidine). Amiodarone and sotalol appear to be at least as effective as drugs with predominant Na+ channel–blocking properties in both atrial and ventricular arrhythmias.

"Pure" action potential–prolonging drugs (e.g., dofetilide and ibutilide) also are available (Murray, 1998; Torp-Pedersen et al., 1999).

### Toxicity of Drugs That Prolong the Action Potential

Most of these agents disproportionately prolong cardiac action potentials and the QT interval when underlying heart rate is slow and can cause torsades de pointes (Table 30–1, Figure 30–9). While this effect usually is seen with QT-prolonging antiarrhythmic drugs, it can occur more rarely...
with drugs that are used for noncardiac indications. For such agents, the risk of torsades de pointes may become apparent only after widespread use postmarketing, and recognition of this risk has been a common cause for drug withdrawal (Roden, 2004). Sex hormones modify cardiac ion channels and help account for the clinically observed increased incidence of drug-induced torsades de pointes in women (Tadros et al., 2014).

**Ca**²⁺ Channel Block

The major electrophysiological effects resulting from block of cardiac Ca**²⁺** channels are in nodal tissues. Dihydropyridinides, such as nifedipine, which are used commonly in angina and hypertension (see Chapters 27 and 28), preferentially block Ca**²⁺** channels in vascular smooth muscle; their cardiac electrophysiological effects, such as heart rate acceleration, result principally from reflex sympathetic activation secondary to peripheral vasodilation. Only verapamil, diltiazem, and bepridil (no longer available in the U.S.) block Ca**²⁺** channels in cardiac cells at clinically used doses. These drugs generally slow heart rate (Figure 30–10A), although hypotension, if marked, can cause reflex sympathetic activation and tachycardia. The velocity of AV nodal conduction decreases, so the PR interval increases. AV nodal block occurs as a result of decremental conduction, as well as increased AV nodal refractoriness. These effects form the basis of the antiarrhythmic actions of Ca**²⁺** channel blockers in reentrant arrhythmias whose circuit involves the AV node, such as AV reentrant tachycardia (Figure 30–7).

Another important indication for antiarrhythmic therapy is to reduce the ventricular rate in atrial flutter or fibrillation. Parenteral verapamil and diltiazem are approved for temporary control of rapid ventricular rate in atrial fibrillation and for rapid conversion of PSVT to sinus rhythm (where their use has largely been supplanted by adenosine). Oral verapamil or diltiazem may be used to control the ventricular rate in chronic atrial flutter or fibrillation and for prophylaxis of repetitive PSVT. Unlike β blockers, Ca**²⁺** channel blockers have not been shown to reduce mortality after myocardial infarction (Singh, 1990). In contrast to other Ca**²⁺** channel blockers, bepridil increases action potential duration in many tissues and can exert an antiarrhythmic effect in atria and ventricles. However, because bepridil can cause torsades de pointes, it is not prescribed widely and has been discontinued in the U.S.

**Verapamil and Diltiazem**

The major adverse effect of intravenous verapamil or diltiazem is hypotension, particularly with bolus administration. This was a particular problem when the drugs were used mistakenly in patients with ventricular tachycardia (in which Ca**²⁺** channel blockers usually are not effective) misdiagnosed as PSVT; the drugs are now rarely used for this indication. Hypotension also is frequent in patients receiving other vasodilators and in patients with underlying left ventricular dysfunction, which the drugs can exacerbate. Severe sinus bradycardia or AV block also occurs, especially in susceptible patients, such as those also receiving β blockers. With oral therapy, these adverse effects tend to be less severe. Constipation can occur with oral verapamil.

Verapamil is prescribed as a racemate. t-Verapamil is the more potent Ca**²⁺** channel blocker. However, with oral therapy, the t-enantiomer undergoes more extensive first-pass hepatic metabolism. For this reason, a given concentration of verapamil prolongs the PR interval to a greater extent when administered intravenously (where concentrations of the t- and d-enantiomers are equivalent) than when administered orally. Diltiazem also undergoes extensive first-pass hepatic metabolism, and both drugs have metabolites that exert Ca**²⁺** channel-blocking actions. In clinical practice, adverse effects during therapy with verapamil or diltiazem are determined largely by underlying heart disease and concomitant therapy; plasma concentrations of these agents are not measured routinely. Both drugs can increase serum digoxin concentration, although the magnitude of this effect is variable; excess slowing of ventricular response may occur in patients with atrial fibrillation.

**Blockade of β Adrenergic Receptors**

β Adrenergic stimulation increases the magnitude of the Ca**²⁺** current and slows its inactivation; increases the magnitude of the repolarizing current I_{kr}; increases pacemaker current (thereby increasing sinus rate; DiFrancesco, 1993); increases the Ca**²⁺** stored in the SR (thereby increasing likelihood of spontaneous Ca**²⁺** release and DADs); and under pathophysiological conditions, can increase both DAD- and EAD-mediated arrhythmias. The increases in plasma epinephrine associated with severe stress (e.g., acute myocardial infarction or resuscitation after cardiac arrest) lower serum K⁺, especially in patients receiving chronic diuretic therapy. β blockers inhibit these effects and can be antiarrhythmic by reducing heart rate, decreasing intracellular Ca**²⁺** overload, and inhibiting afterdepolarization-mediated automaticity. Epinephrine-induced hypokalemia appears to be mediated by β₂ adrenergic receptors and is blocked by “noncardioselective” antagonists such as propranolol (see Chapter 12). In acutely ischemic tissue, β blockers increase the energy required to fibrillate the heart, an antiarrhythmic action. These effects may contribute to the reduced short-term and long-term mortality observed in trials of chronic therapy with β blockers—after myocardial infarction (Singh, 1990).

As with Ca**²⁺** channel blockers and digitalis, β blockers increase AV nodal conduction time (increased PR interval) and prolong AV nodal refractoriness; hence, they are useful in terminating reentrant arrhythmias that involve the AV node and in controlling ventricular response in atrial fibrillation or flutter. In many (but not all) patients with the congenital LQTS, in all patients with the CPVT syndrome, as well as in many other patients, arrhythmias are triggered by physical or emotional stress; β blockers may be useful in these cases (Roden and Spooner, 1999; Schwartz et al., 2000). β blockers also reportedly are effective in controlling arrhythmias owing to Na⁺ channel blockers; this effect may be due in part to slowing of the heart rate, which then decreases the extent of rate-dependent conduction slowing by Na⁺ channel block.

Adverse effects of β blockade include fatigue, bronchodspasm, hypotension, impotence, depression, aggravation of heart failure, worsening of symptoms owing to peripheral vascular disease, and masking of the symptoms of hypoglycemia in diabetic patients (see Chapter 12). In patients with arrhythmias owing to e.g., sympathetic stimulation (e.g., pheochromocytoma or clonidine withdrawal), β blockers can result in unopposed a adrenergic stimulation, with resulting severe hypertension or a adrenergic–mediated arrhythmias. In such patients, arrhythmias should be treated with both α and β blockers or with a drug such as labetalol that combines α- and β-blocking properties. Abrupt discontinuation of chronic β-blocker therapy can lead to “rebound” symptoms, including hypertension, increased angina, and arrhythmias; thus, β blockers are tapered over 2 weeks prior to discontinuation of chronic therapy (see Chapters 12 and 27–29).

**Selected β Blockers**

It is likely that most β blockers share antiarrhythmic properties. Some, such as propranolol, also exert Na⁺ channel–blocking effects at high concentrations. Similarly, drugs with intrinsic sympathomimetic activity may be less useful as antiarrhythmics (Singh, 1990). Acebutolol is as effective as quinidine in suppressing ventricular ectopic beats, an arrhythmia that many clinicians no longer treat. Sotalol (see its discussion in a separate section) is more effective for many arrhythmias than other β blockers, probably because of its K⁺ channel–blocking actions. Esmolol (see separate discussion that follows) is a β₁-selective agent that has a very short elimination half-life. Intravenous esmolol is useful in clinical situations in which immediate β adrenergic blockade is desired. Some β blockers (e.g., propranolol) are CYP2D6 substrates; thus, efficacy may vary across individuals (CYP2D6 substrates). Many clinicians now favor nadolol when β blockade is needed in congenital arrhythmias (CPVT, LQTS).
1. Identify and Remove Precipitating Factors

Factors that commonly precipitate cardiac arrhythmias include hypoxia, electrolyte disturbances (especially hypokalemia), myocardial ischemia, and certain drugs. Antiarrhythmics, including cardiac glycosides, are not the only drugs that can precipitate arrhythmias (Table 30–1). For example, theophylline can cause multifocal atrial tachycardia, which sometimes can be managed simply by reducing the dose of theophylline. Torsades de pointes can arise during therapy not only with action potential–prolonging antiarrhythmics but also with other “noncardiovascular” drugs not ordinarily classified as having effects on ion channels (Roden, 2004). The incidence can vary from 1% to 3% in patients receiving sotalol or dofetilide to very rare (<1/50,000) with some noncardiovascular drugs. Drugs with a very wide range of clinical indications have been implicated: These include some antibiotics (including antibacterials, antiproteozoa, antivirals, and antifungals), antipsychotics, antihistamines, antidepressants, and methadone. The website https://crediblemeds.org maintains a list of drugs (and levels of evidence) that have been implicated in this adverse effect.

2. Establish the Goals of Treatment

Some Arrhythmias Should Not Be Treated: The CAST Example

Abnormalities of cardiac rhythm are readily detectable by a variety of recording methods. However, the mere detection of an abnormality does not equate with the need for therapy. This was illustrated in CAST. The presence of asymptomatic ventricular ectopic beats is a known marker for increased risk of sudden death owing to VF in patients convalescing from myocardial infarction. In CAST, patients whose ventricular ectopic beats were suppressed by the potent Na+ channel blocker encainide (no longer marketed) or flecainide were randomly assigned to receive those drugs or placebo. Unexpectedly, the mortality rate was 2- to 3-fold higher among patients treated with the drugs than those treated with placebo (Echt et al., 1991). While the explanation for this effect is not known, several lines of evidence suggest that, in the presence of these drugs, transient episodes of myocardial ischemia or sinus tachycardia can cause marked conduction slowing (because these drugs have a very long τ_{recovery}, resulting in fatal reentrant ventricular tachyarrhythmias.

One consequence of this pivotal clinical trial was to reemphasize the concept that therapy should be initiated only when a clear benefit to the patient can be identified. When symptoms are obviously attributable to an ongoing arrhythmia, there usually is little doubt that termination of the arrhythmia will be beneficial; when chronic therapy is used to prevent recurrence of an arrhythmia, the risks may be greater (Roden, 1994).

Among the antiarrhythmic drugs discussed here, only β adrenergic blockers and, to a lesser extent, amiodarone (Connolly, 1999) demonstrably reduce mortality during long-term therapy.

Symptoms Due to Arrhythmias

Some patients with an arrhythmia may be asymptomatic; in this case, establishing any benefit for treatment will be difficult. Some patients may present with presyncope, syncope, or even cardia arrest, which may be due to brady- or tachyarrhythmias. Other patients may present with a sensation of irregular heartbeats (i.e., palpitations) that can be minimally symptomatic in some individuals and incapacitating in others. The irregular heartbeats may be due to intermittent premature contractions or to sustained arrhythmias such as atrial fibrillation (which results in an irregular ventricular rate) (Figure 30–9). Finally, patients may present with symptoms owing to decreased cardiac output attributable to arrhythmias. The most common symptom is breathlessness either at rest or on exertion. Occasionally, sustained or frequent tachyarrhythmias may produce no “arrhythmia” symptoms (such as palpitations) but will depress contractile function; these patients may present with heart failure due to “tachycardia-induced cardiomyopathy”, a condition that can be controlled by treating the arrhythmia.

Choosing Among Therapeutic Approaches

In choosing among available therapeutic options, it is important to establish clear therapeutic goals. For example, three options are available in patients with atrial fibrillation: (1) reduce the ventricular response using AV nodal-blocking agents such as digitalis, verapamil, diltiazem, or β blockers (Table 30–1); (2) restore and maintain normal rhythm using drugs such as flecainide or amiodarone; or (3) decide not to implement antiarrhythmic therapy, especially if the patient truly is asymptomatic. Most patients with atrial fibrillation also benefit from anticoagulation to reduce stroke incidence regardless of symptoms (Dzeshka and Lip, 2015) (see Chapter 32).

Factors that contribute to choice of therapy include not only symptoms but also the type and extent of structural heart disease, the QT interval prior to drug therapy, the coexistence of conduction system disease, and the presence of noncardiac diseases (Table 30–4). In the rare patient with the WPW syndrome and atrial fibrillation, the ventricular response can be extremely rapid and can be accelerated paradoxically with digitals or Ca2+ channel blockers; deaths owing to drug therapy have been reported under these circumstances.

The frequency and reproducibility of arrhythmia should be established prior to initiating therapy because inherent variability in the occurrence of arrhythmias can be confused with a beneficial or adverse drug effect. Techniques for this assessment include recording cardiac rhythm for prolonged periods or evaluating the response of the heart to artificially induced premature beats. It is important to recognize that drug therapy may be only partially effective. A marked decrease in the duration...
of paroxysms of atrial fibrillation may be sufficient to render a patient asymptomatic even if an occasional episode still can be detected.

3. Minimize Risks

Antiarrhythmic Drugs Can Cause Arrhythmias

One well-recognized risk of antiarrhythmic therapy is the possibility of provoking new arrhythmias, with potentially life-threatening consequences. Antiarrhythmic drugs can provoke arrhythmias by different mechanisms (Table 30–1). These drug-provoked arrhythmias must be recognized because further treatment with antiarrhythmic drugs often exacerbates the problem, whereas withdrawal of the causative agent is curative. Thus, establishing a precise diagnosis is critical, and targeting therapies at underlying mechanisms of the arrhythmias may be required. For example, treating a ventricular tachycardia with verapamil not only may be ineffective but also can cause catastrophic cardiovascular collapse.

Monitoring of Plasma Concentration

Some adverse effects of antiarrhythmic drugs result from excessive plasma drug concentrations. Measuring plasma concentration and adjusting the dose to maintain the concentration within a prescribed therapeutic range may minimize some adverse effects. In many patients, serious adverse reactions relate to interactions involving antiarrhythmic drugs (often at usual plasma concentrations), transient factors such as electrolyte disturbances or myocardial ischemia, and the type and extent of the underlying heart disease (Roden, 1994). Factors such as generation of unmeasured active metabolites, variability in elimination of enantiomers (which may exert differing pharmacological effects), and disease- or enantiomer-specific abnormalities in drug binding to plasma proteins can complicate the interpretation of plasma drug concentrations.

Patient-Specific Contraindications

Another way to minimize the adverse effects of antiarrhythmic drugs is to avoid certain drugs in certain patient subsets altogether. For example, patients with a history of congestive heart failure are particularly prone to develop heart failure during disopyramide therapy. In other cases, adverse effects of drugs may be difficult to distinguish from exacerbations of underlying disease. Amiodarone may cause interstitial lung disease; its use therefore is undesirable in a patient with advanced pulmonary disease in whom the development of this potentially fatal adverse effect would be difficult to detect. Specific diseases that constitute relative or absolute contraindications to specific drugs are listed in Table 30–4.

4. Consider the Electrophysiology of the Heart as a “Moving Target”

Cardiac electrophysiology varies dynamically in response to external influences such as changing autonomic tone, myocardial ischemia, and myocardial stretch (Priori et al., 1999). For example, myocardial ischemia results in changes in extracellular K⁺ that make the resting potential less negative, inactivate Na⁺ channels, decrease Na⁺ current, and slow conduction. In addition, myocardial ischemia can result in the formation and release of metabolites such as lysophosphatidylcholine, which can alter ion channel function; ischemia also may activate channels that otherwise are quiescent, such as the ATP-inhibited K⁺ channels. Thus, in response to myocardial ischemia, a normal heart may display changes in resting potential, conduction velocity, intracellular Ca⁺⁺ concentrations, and repolarization, any one of which then may create arrhythmias or alter response to antiarrhythmic therapy.

Antiarrhythmic Drugs

Summaries of important electrophysiological and pharmacokinetic features of the drugs considered are presented in Tables 30–3 and 30–5. Ca⁺⁺ channel blockers and β blockers are discussed in Chapters 12 and 27 to 29. The drugs are presented in alphabetical order. Prescribing patterns have changed over the past several decades in part because fewer suppliers market older drugs, such as quinidine or procainamide, which are therefore increasingly difficult to obtain, a problem for a small number of patients who may still benefit from treatment (Inama et al., 2010; Viskin et al., 2013).

Adenosine

Adenosine is a naturally occurring nucleoside that is administered as a rapid intravenous bolus for the acute termination of reentrant supraventricular arrhythmias (Link, 2012). Rare cases of ventricular tachycardia in patients with otherwise-normal hearts are thought to be DAD mediated and can be terminated by adenosine. Adenosine also has been used to produce controlled hypotension during some surgical procedures and in the diagnosis of coronary artery disease. Intravenous ATP appears to produce effects similar to those of adenosine.

Pharmacological Effects

The effects of adenosine are mediated by its interaction with specific G protein–coupled adenosine receptors. Adenosine activates acetylcholine-sensitive K⁺ current in the atrium and sinus and AV nodes, resulting in shortening of action potential duration, hyperpolarization, and slowing of normal automaticity (Figure 30–10C). Adenosine also inhibits the electrophysiological effects of increased intracellular cyclic AMP that occur with sympathetic stimulation. Because adenosine thereby reduces Ca⁺⁺ currents, it can be antiarrhythmic by increasing AV nodal refractoriness and by inhibiting DADs elicited by sympathetic stimulation.

Administration of an intravenous bolus of adenosine to humans transiently slows sinus rate and AV nodal conduction velocity and increases AV nodal refractoriness. A bolus of adenosine can produce transient sympathetic activation by interacting with carotid baroreceptors; a continuous infusion can cause hypotension.

Adverse Effects

A major advantage of adenosine therapy is that adverse effects are short-lived because the drug is transported into cells and deaminated so rapidly. Transient asystole (lack of any cardiac rhythm whatsoever) is common but usually lasts less than 5 sec and is in fact the therapeutic goal. Most patients feel a sense of chest fullness and dyspnea when therapeutic doses (6 to 12 mg) of adenosine are administered. Rarely, an adenosine bolus can precipitate atrial fibrillation, presumably by heterogeneously shortening atrial action potentials, or bronchospasm.

Clinical Pharmacokinetics

Adenosine is eliminated with a half-life of seconds by carrier-mediated uptake, which occurs in most cell types, including the endothelium, followed by metabolism by adenosine deaminase. Adenosine probably is the only drug whose efficacy requires a rapid bolus dose, preferably through a large central intravenous line; slow administration results in elimination of the drug prior to its arrival at the heart.

The effects of adenosine are potentiated in patients receiving dipyridamole, an adenosine-uptake inhibitor, and in patients with cardiac transplants owing to denervation hypersensitivity. Methyloxanthines (see Tables 14–7, 40–2, and 40–3, and Figure 40–5) such as theophylline and caffeine block adenosine receptors; therefore, larger-than-usual doses are required to produce an antiarrhythmic effect in patients who have consumed these agents in beverages or as therapy.

Amiodarone

Amiodarone exerts a multiplicity of pharmacological effects, none of which is clearly linked to its arrhythmia-suppressing properties. Amiodarone is a structural analogue of thyroid hormone, and some of its antiarrhythmic...
actions and its toxicity may be attributable to interaction with nuclear thyroid hormone receptors. Amiodarone is highly lipophilic, is concentrated in many tissues, and is eliminated extremely slowly; consequently, adverse effects may resolve very slowly. In the U.S., the drug is indicated for oral therapy in patients with recurrent ventricular tachycardia or VF resistant to other drugs. In addition, the intravenous form is a first-line drug for management of ventricular tachycardia or VF causing cardiac arrest (Dorian et al., 2002). Trials of oral amiodarone have shown a modest beneficial effect on mortality after acute myocardial infarction (Amiodarone Trials Meta-Analysis Investigators, 1997). Despite uncertainties about its mechanisms of action and the potential for serious toxicity, amiodarone is used widely in the treatment of common arrhythmias such as atrial fibrillation (Roy et al., 2000).

**Pharmacological Effects**

Studies of the acute effects of amiodarone in in vitro systems are complicated by its insolubility in water, necessitating the use of solvents such as dimethyl sulfoxide, which can have electrophysiological effects on its own. Amiodarone’s effects may be mediated by perturbation of the lipid environment of the ion channels. Amiodarone blocks inactivated Na+ channels and has a relatively rapid rate of recovery (time constant = 1.6 sec) from block. It also decreases Ca2+ current and transient outward delayed rectifier and inward rectifier K+ currents and exerts a non-competitive adrenergic-blocking effect. Amiodarone potently inhibits abnormal automaticity and, in most tissues, prolongs action potential duration. Amiodarone decreases conduction velocity by Na+ channel block and by a poorly understood effect on cell-cell coupling that may be especially important in diseased tissue. Prolongations of the PR, QRS, and QT intervals and sinus bradycardia are frequent during chronic therapy. Amiodarone prolongs refractoriness in all cardiac tissues; Na+ channel block, delayed repolarization owing to K+ channel block, and inhibition of cell-cell coupling all may contribute to this effect.

**Adverse Effects**

Hypotension owing to vasodilation and depressed myocardial performance are frequent with the intravenous form of amiodarone and may be due in part to the solvent. While depressed contractility can occur during long-term oral therapy, it is unusual. Despite administration of high doses that would cause serious toxicity if continued long term, adverse effects are unusual during oral drug-loading regimens, which typically require several weeks. Occasional patients develop nausea during the loading phase, which responds to a decrease in daily dose.

Adverse effects during long-term therapy reflect both the size of daily maintenance doses and the cumulative dose, suggesting that tissue accumulation may be responsible. The most serious adverse effect during chronic amiodarone therapy is pulmonary fibrosis, which can be rapidly progressive and fatal. Underlying lung disease, doses of 400 mg/d or more, and recent pulmonary insults such as pneumonia appear to be risk factors. Serial chest X-rays or pulmonary function studies may detect early amiodarone toxicity, but monitoring plasma concentrations has not been useful. With low doses, such as 200 mg/d or less as used in atrial fibrillation, pulmonary toxicity is less common (Zimetbaum, 2007). Other adverse effects during long-term therapy include corneal microdeposits (which often are asymptomatic), hepatic dysfunction, neuromuscular symptoms (most commonly peripheral neuropathy or proximal muscle weakness), photosensitivity, and hypo- or hyperthyroidism. The multiple effects of amiodarone on thyroid function are discussed further in Chapter 43. Treatment consists of withdrawal of the drug and supportive measures, including corticosteroids, for life-threatening pulmonary toxicity; reduction of dosage may be sufficient if the drug is deemed necessary and the adverse effect is not life threatening. Despite the marked QT prolongation and bradycardia typical of chronic amiodarone therapy, torsades de pointes and other drug-induced tachyarrhythmias are unusual.

**Clinical Pharmacokinetics**

Amiodarone’s oral bioavailability is about 30%, presumably due to poor absorption. This incomplete bioavailability is important in calculating equivalent dosing regimens when converting from intravenous to oral therapy. The drug distributes into lipid; heart tissue-to-plasma concentration ratios of greater than 20:1 and lipid-to-plasma ratios of greater than 300:1 have been reported. After the initiation of amiodarone therapy, increases in refractoriness, a marker of pharmacological effect, require several weeks to develop. Amiodarone undergoes hepatic metabolism by CYP3A4 to desethyl-amiodarone, a metabolite with pharmacological effects similar to those of the parent drug. When amiodarone therapy is withdrawn from a patient who has been receiving therapy for several years, plasma concentrations decline with a half-life of weeks to months. The mechanisms of amiodarone and desethyl-amiodarone elimination are not well established.

A therapeutic plasma amiodarone concentration range of 0.5 to 2 μg/mL has been proposed. However, efficacy apparently depends as much on duration of therapy as on plasma concentration, and elevated plasma concentrations do not predict toxicity. Because of amiodarone’s slow accumulation in tissue, a high-dose oral loading regimen (e.g., 800 to 1600 mg/d) usually is administered for several weeks before maintenance therapy is started. The maintenance dose is adjusted based on adverse effects and the arrhythmias being treated. If the presenting arrhythmia is life threatening, dosages of more than 300 mg/d normally are used unless unequivocal toxicity occurs. On the other hand, maintenance doses of 200 mg/d or less are used if recurrence of an arrhythmia would be tolerated, as in patients with atrial fibrillation, because amiodarone slows the ventricular rate during atrial fibrillation.

Dosage adjustments are not required in hepatic, renal, or cardiac dysfunction. Amiodarone potently inhibits the hepatic metabolism or renal elimination of many compounds. Mechanisms identified to date include inhibition of CYP3A4, CYP2C9, and P-glycoprotein (see Chapters 5 and 6). Dosages of warfarin, other antiarrhythmics (e.g., flecainide, procainamide, and quinidine), or digoxin usually require reduction during amiodarone therapy.

**Bretylium**

Bretylium is a quaternary ammonium compound that prolongs cardiac action potentials and interferes with reuptake of norepinephrine by sympathetic neurons. In the past, bretylium was used to treat VF and prevent its recurrence; the drug is currently not available in the U.S.

**Digoxin**
Pharmacological Effects

Digitalis glycosides exert positive inotropic effects and have been used in heart failure; now, they are rarely prescribed (see Chapter 29). Their inotropic action results from increased intracellular Ca²⁺, which also forms the basis for arrhythmias related to cardiac glycoside intoxication. Cardiac glycosides increase phase 4 slope (i.e., increase the rate of automaticity), especially if [K] is low. These drugs (e.g., digoxin) also exert prominent vagotonic actions, resulting in inhibition of Ca²⁺ currents in the AV node and activation of acetylcholine-mediated K⁺ currents in the atrium. Thus, the major “indirect” electrophysiological effects of cardiac glycosides are hyperpolarization, shortening of atrial action potentials, and increases in AV nodal refractoriness. The last action accounts for the utility of digoxin in terminating reentrant arrhythmias involving the AV node and in controlling ventricular response in patients with atrial fibrillation. Cardiac glycosides may be especially useful in the last situation because many such patients have heart failure, which can be exacerbated by other AV nodal-blocking drugs such as Ca²⁺ channel blockers or β blockers. However, sympathetic drive is increased markedly in many patients with advanced heart failure, so digitalis is not very effective in decreasing the rate; on the other hand, even a modest decrease in rate can ameliorate heart failure.

Similarly, in other conditions in which high sympathetic tone drives rapid AV conduction (e.g., chronic lung disease and many congestive heart failure states), digoxin therapy may be only marginally effective in slowing the rate. In heart transplant patients, in whom innervation has been ablated, cardiac glycosides are ineffective for rate control. Increased sympathetic activity and hypoxia can potentiate digitalis-induced changes in automaticity and DADs, thus increasing the risk of digitalis toxicity. A further complicating feature in thyrotoxicosis is increased digoxin clearance.

The major ECG effects of cardiac glycosides are PR prolongation and a nonspecific alteration in ventricular repolarization (manifested by depression of the ST segment), whose underlying mechanism is not well understood.

Adverse Effects

Because of the low therapeutic index of cardiac glycosides, their toxicity is a common clinical problem (see Chapter 29). Arrhythmias, nausea, disturbances of cognitive function, and blurred or yellow vision are the usual manifestations. Elevated serum concentrations of digitalis, hypoxia (e.g., owing to chronic lung disease), and electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia, and hypercalcemia) predispose patients to digitalis-induced arrhythmias. While digitalis intoxication can cause virtually any arrhythmia, certain types of arrhythmias are characteristic. Arrhythmias that should raise a strong suspicion of digitalis intoxication are those in which DAD-related tachycardias occur along with impairment of sinus node or AV nodal function. Atrial tachycardia with AV block is classic, but ventricular bigeminy (sinus beats alternating with beats of ventricular origin), “bidirectional” ventricular tachycardia (a rare entity), AV junctional tachycardias, and various degrees of AV block also can occur. With severe intoxication (e.g., with suicidal ingestion), severe hyperkalemia owing to poisoning of Na⁺, K⁺-ATPase and profound bradyarrhythmias, which may be unresponsive to pacing therapy, are seen. In patients with elevated serum digitalis levels, the risk of precipitating VF by DC cardioversion probably is increased; in those with therapeutic blood levels, DC cardioversion can be used safely.

Minor forms of cardiac glycoside intoxication may require no specific therapy beyond monitoring cardiac rhythm until symptoms and signs of toxicity resolve. Sinus bradycardia and AV block often respond to intravenous atropine, but the effect is transient. Mg²⁺ has been used successfully in some cases of digitalis-induced tachycardia. Any serious arrhythmia should be treated with antidigoxin Fab fragments (Digibind, Digifab), which are highly effective in binding digoxin and digitoxin and greatly enhance their renal excretion (see Chapter 29). Serum glycoside concentrations rise markedly with antidigitalis antibodies, but these represent bound (pharmacologically inactive) drug. Temporary cardiac pacing may be required for advanced sinus node or AV node dysfunction. Digoxin exerts direct arterial vasconstrictor effects, which can be especially deleterious in patients with advanced atherosclerosis who receive intravenous drug: mesenteric and coronary ischemia have been reported.

Clinical Pharmacokinetics

The only digitalis glycoside used in the U.S. is digoxin. Digitoxin (various generic preparations) also is used for chronic oral therapy outside the U.S. Digoxin tablets are incompletely (75%) bioavailable. In some patients, intestinal microflora may metabolize digoxin, markedly reducing bioavailability. In these patients, higher-than-usual doses are required for clinical efficacy; toxicity is a serious risk if antibiotics are administered that destroy intestinal microflora. Inhibition of P-glycoprotein (see further discussion) also may play a role in cases of toxicity. Digoxin is 20% to 30% protein bound. The antiarrhythmic effects of digoxin can be achieved with intravenous or oral therapy. However, digoxin undergoes relatively slow distribution to effector site(s); therefore, even with intravenous therapy, there is a lag of several hours between drug administration and the development of measurable antiarrhythmic effects such as PR interval prolongation or slowing of the ventricular rate in atrial fibrillation. To avoid intoxication, a loading dose of approximately 0.6 to 1 mg digoxin is administered over 24 h. Measurement of postdistribution serum digoxin concentration and adjustment of the daily dose (0.0625 to 0.5 mg) to maintain concentrations of 0.5 to 2 ng/mL are useful during chronic digoxin therapy (Table 30–5). Some patients may require and tolerate higher concentrations, but with an increased risk of adverse effects.

The elimination half-life of digoxin ordinarily is about 36 h, so maintenance doses are administered once daily. Renal elimination of unchanged drug accounts for about 80% of digoxin elimination. Digoxin doses should be reduced (or dosing interval increased) and serum concentrations monitored closely in patients with impaired excretion owing to renal failure or in patients who are hypothyroid. Digitoxin undergoes primarily hepatic metabolism and may be useful in patients with fluctuating or advanced renal dysfunction. Digitoxin metabolism is accelerated by drugs such as phenytoin and rifampin that induce hepatic metabolism. Digitoxin's elimination half-life is even longer than that of digoxin (about 7 days); it is highly protein bound, and its therapeutic range is 10 to 30 ng/mL.

Amiodarone, quinidine, verapamil, diltiazem, cyclosporine, itraconazole, propafenone, and flecainide decrease digoxin clearance, likely by inhibiting P-glycoprotein, the major route of digoxin elimination (Fromm et al., 1999). New steady-state digoxin concentrations are approached after four to five half-lives (i.e., in about a week). Digitalis toxicity results so often with quinidine or amiodarone that it is routine to decrease the dose if necessary. Hypokalemia, which can be caused by many drugs (e.g., diuretics, amphotericin B, and corticosteroids), will potentiate digitalis-induced arrhythmias.

Disopyramide

Disopyramide exerts electrophysiological effects very similar to those of quinidine, but the drugs have different adverse effect profiles. Disopyramide can be used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or VF. Because of its negative inotropic effects, it is sometimes used in hypertrophic cardiomyopathy. Disopyramide is prescribed as a racemate.

Pharmacological Actions and Adverse Effects

The in vitro electrophysiological actions of S-(-)-disopyramide are similar to those of quinidine. The R(-)-enantiomer produces similar Na⁺ channel block but does not prolong cardiac action potentials. Unlike quinidine, racemic disopyramide does not antagonize a adrenergic receptors, but does exert prominent anticholinergic actions that account for many of its adverse effects. These include precipitation of glaucoma, constipation, dry mouth, and urinary retention; the last is most common in males with prostatism but also can occur in females. Disopyramide can cause torsades de pointes and also commonly depresses contractility, which can precipitate heart failure. In patients with hypertrophic cardiomyopathy, this depression contractility may be exploited to therapeutic
advantage to decrease dynamic outflow tract obstruction (Sherrid and Arabadjian, 2012).

**Clinical Pharmacokinetics**

Disopyramide is well absorbed. Binding to plasma proteins is concentration dependent, so a small increase in total concentration may represent a disproportionately larger increase in free drug concentration. Disopyramide is eliminated by both hepatic metabolism (to a weakly active metabolite) and renal excretion of unchanged drug. The dose should be reduced in patients with renal dysfunction. Higher-than-usual dosages may be required in patients receiving drugs that induce hepatic metabolism, such as phenytoin.

**Dofetilide**

Dofetilide prolongs action potentials and the QT interval by potently blocking the \( I_{Kr} \) channel. Increased late Na\(^+\) current, likely due to inhibition of phosphoinositide 3-kinase (Yang et al., 2014), may also contribute. The drug has virtually no extracardiac pharmacological effects. Dofetilide is effective in maintaining sinus rhythm in patients with atrial fibrillation. In the DIAMOND studies (Torp-Pedersen et al., 1999), dofetilide did not affect mortality in patients with advanced heart failure or in those convalescing from acute myocardial infarction. Dofetilide currently is available through a restricted distribution system that includes only physicians, hospitals, and other institutions that have received special educational programs covering proper dosing and in-hospital treatment initiation.

**Adverse Effects**

Torsades de pointes occurred in 1%-3% of patients in clinical trials where strict exclusion criteria (e.g., hypokalemia) were applied and continuous ECG monitoring was used to detect marked QT prolongation in the hospital. Other adverse effects were no more common than with placebo during premarketing clinical trials.

**Clinical Pharmacokinetics**

Most of a dose of dofetilide is excreted unchanged by the kidneys. In patients with mild-to-moderate renal failure, decreases in dosage based on creatinine clearance are required to minimize the risk of torsades de pointes. The drug should not be used in patients with advanced renal failure or with inhibitors of renal cation transport. Dofetilide also undergoes minor hepatic metabolism.

**Dronedarone**

Dronedarone is a noniodinated benzofuran derivative of amiodarone that is FDA-approved for the treatment of atrial fibrillation and atrial flutter. In randomized placebo-controlled trials, it was effective in maintaining sinus rhythm and reducing the ventricular response rate during episodes of atrial fibrillation (Patel et al., 2009). Compared to amiodarone, dronedarone treatment is associated with significantly fewer adverse events, but it is also significantly less effective in maintaining sinus rhythm. Dronedarone decreased hospital admissions compared to placebo in patients with a history of atrial fibrillation (Hohnloser et al., 2009). In other studies, however, the drug increased mortality in patients with permanent atrial fibrillation (Connolly et al., 2011) and in those with severe heart failure (Kober et al., 2008).

**Pharmacological Effects**

Like amiodarone, dronedarone is a blocker of multiple ion currents, including the rapidly activating delayed-rectifier K\(^+\) current \( I_{Kr} \), the slowly activating delayed-rectifier K\(^+\) current \( I_{Kr} \), the inward rectifier K\(^+\) current \( I_{Kr} \), the acetylcholine-activated K\(^+\) current, the peak Na\(^+\) current, and the L-type Ca\(^{2+}\) current. It has stronger antiadrenergic effects than amiodarone.

**Adverse Effects and Drug Interactions**

The most common adverse reactions are diarrea, nausea, abdominal pain, vomiting, and asthenia. Dronedarone causes dose-dependent prolongation of the QTc interval, but torsades de pointes is rare. Dronedarone is metabolized by CYP3A and is a moderate inhibitor of CYP3A, CYP2D6, and P-glycoprotein. Potent CYP3A4 inhibitors such as ketoconazole may increase dronedarone exposure by as much as 25-fold. Consequently, dronedarone should not be coadministered with potent CYP3A4 inhibitors (e.g., antifungals, macrolide antibiotics). Coadministration with other drugs metabolized by CYP2D6 (e.g., metoprolol) or P-glycoprotein (e.g., digoxin) may result in increased drug concentrations. Dronedarone may cause severe liver injury; the FDA recommends monitoring of hepatic enzymes.

**Esmolol**

Esmolol is a \( \beta_1 \)-selective agent that is metabolized by erythrocyte esterases and so has a very short elimination half-life (9 min). Intravenous esmolol is useful in clinical situations in which immediate \( \beta \) adrenergic blockade is desired (e.g., for rate control of rapidly conducted atrial fibrillation). Because of esmolol's very rapid elimination, adverse effects due to \( \beta \) adrenergic blockade—should they occur—dissipate rapidly when the drug is stopped. Although methanol is a metabolite of esmolol, methanol intoxication has not been a clinical problem. The pharmacology of esmolol is described in further detail in Chapter 12.

**Flecainide**

The effects of flecainide therapy are thought to be attributable to the drug's very long \( t_{1/2} \) from Na\(^+\) channel block. Suppression of DADs triggered by RyR2 Ca\(^{2+}\) release may also contribute to flecainide's antiarrhythmic effect. In CAST, flecainide increased mortality in patients convalescing from myocardial infarction (Echt et al., 1991). However, it continues to be approved for certain arrhythmias in patients in whom structural heart disease is absent (Henthorn et al., 1991); this includes the maintenance of sinus rhythm in patients with supraventricular arrhythmias, including atrial fibrillation, as well as life-threatening ventricular arrhythmias, such as sustained ventricular tachycardia. Clinical case series suggested long-term flecainide efficacy in two congenital ventricular arrhythmia syndromes: type 3 LQTS due to mutations that cause late Na\(^+\) currents and CPVT due to mutations that cause "leaky" RyR2 SR Ca\(^{2+}\) release channels. Supported by data from a recent randomized clinical trial (Kannankeril et al., 2017), flecainide has become the drug of choice for preventing arrhythmias in CPVT patients uncontrolled by \( \beta \) blockers.

**Pharmacological Effects**

Flecainide blocks Na\(^+\) current and delayed rectifier K\(^+\) current \( I_{Kr} \) in vitro at similar concentrations, 1 to 2 μM. It also blocks Ca\(^{2+}\) currents in vitro. Action potential duration is shortened in Purkinje cells, probably owing to block of late-opening Na\(^+\) channels, but is prolonged in ventricular cells, probably owing to block of delayed rectifier current. Flecainide does not cause EADs in vitro but has been associated with rare cases of torsades de pointes. In atrial tissue, flecainide disproportionately prolongs action potentials at fast rates, an especially desirable antiarrhythmic drug effect; this effect contrasts with that of quinidine, which prolongs atrial action potentials to a greater extent at slower rates. Flecainide prolongs the duration of PR, QRS, and QT intervals even at normal heart rates. Flecainide is also an open channel blocker of RyR2 Ca\(^{2+}\) release channels and prevents arhythmogenic Ca\(^{2+}\) release from the SR and hence DADs in isolated myocytes (Hilliard et al., 2010). The RyR2 channel block by flecainide targets directly the underlying molecular defect in patients with mutations in the RyR2 gene and the cardiac calsequestrin gene, which may explain why flecainide suppresses ventricular arrhythmias in patients with CPVT refractory to \( \beta \) blocker therapy (Watanabe et al., 2009; Kannankeril et al., 2017).

**Adverse Effects**

Flecainide produces few subjective complaints in most patients; dose-related blurred vision is the most common noncardiac adverse effect. It can exacerbate congestive heart failure in patients with depressed left ventricular performance. The most serious adverse effects are provocation or exacerbation of potentially lethal arrhythmias. These include acceleration of ventricular rate in patients with atrial flutter, increased frequency of episodes of reentrant ventricular tachycardia, and increased mortality in patients convalescing from myocardial infarction. As discussed previously, it is likely that all these effects can be attributed to Na\(^+\).
channel block. Flecainide also can cause heart block in patients with conduction system disease.

**Clinical Pharmacokinetics**

Flecainide is well absorbed. The elimination $t_{1/2}$ is shorter with urinary acidification (10 h) than with urinary alkalinization (17 h), but it is nevertheless sufficiently long to allow dosing twice daily (Table 30–5). Elimination occurs by both renal excretion of unchanged drug and hepatic metabolism to inactive metabolites. The latter is mediated by the polymorphically distributed enzyme CYP2D6. However, even in patients in whom this pathway is absent because of genetic polymorphism or inhibition by other drugs (e.g., quinidine or fluoxetine), renal excretion ordinarily is sufficient to prevent drug accumulation. In the rare patient with renal dysfunction and lack of active CYP2D6, flecainide may accumulate to toxic plasma concentrations. Flecainide is a racemate, but there are no differences in the electrophysiological effects or disposition kinetics of its enantiomers. Some reports have suggested that plasma flecainide concentrations greater than 1 μg/mL should be avoided to minimize the risk of flecainide toxicity; however, in susceptible patients, the adverse electrophysiological effects of flecainide therapy can occur at therapeutic plasma concentrations.

**Ibutilide**

Ibutilide is an $I_{Na}$ blocker that in some systems also activates an inward Na$^+$ current (Murray, 1998). The action potential–prolonging effect of the drug may arise from either mechanism. Ibutilide is administered as a rapid infusion (1 mg over 10 min) for the immediate conversion of atrial fibrillation or flutter to sinus rhythm. The drug’s efficacy rate is higher compared with those in whom it has been present for days. The major toxicity with ibutilide is torsades de pointes, which occurs in up to 6% of patients and requires immediate cardioversion in up to one-third of these. The drug undergoes extensive first-pass metabolism, so it is not used orally. It is eliminated by hepatic metabolism and has a $t_{1/2}$ of 2–12 h (average 6 h).

**Lidocaine**

Lidocaine is a local anesthetic that also is useful in the acute intravenous therapy of ventricular arrhythmias. When lidocaine was administered to all patients with suspected myocardial infarction, the incidence of VF was reduced. However, survival to hospital discharge tended to be decreased, perhaps because of lidocaine-exacerbated heart block or congestive heart failure. Therefore, lidocaine no longer is administered routinely to all patients in coronary care units.

**Pharmacological Effects**

Lidocaine blocks both open and inactivated cardiac Na$^+$ channels. In vitro studies suggested that lidocaine-induced block reflects an increased likelihood that the Na$^+$ channel protein assumes a nonconducting conformation in the presence of drug (Balser et al., 1996). Recovery from block is rapid, so lidocaine exerts greater effects in depolarized (e.g., ischemic) or rapidly driven tissues. Lidocaine is not useful in atrial arrhythmias, possibly because atrial action potentials are so short that the Na$^+$ channel is in the inactivated state only briefly compared with diastolic (recovery) times, which are relatively long. In some studies, lidocaine increased current through inward rectifier channels, but the clinical significance of this effect is not known. Lidocaine can hyperpolarize Purkinje fibers depolarized by low [K$^+$], or stretch; the resulting increased conduction velocity may be antiarrhythmic in reentry.

Lidocaine decreases automaticity by reducing the slope of phase 4 and altering the threshold for excitability. Action potential duration usually is unaffected or is shortened; such shortening may be due to block of the few Na$^+$ channels that inactivate late during the cardiac action potential. Lidocaine usually exerts no significant effect on PR or QRS duration; QT is unaltered or slightly shortened. The drug exerts little effect on hemodynamic function, although rare cases of lidocaine-associated exacerbations of heart failure have been reported, especially in patients with very poor left ventricular function. For additional information on lidocaine, see Chapter 22 on local anesthetics.

**Adverse Effects**

When a large intravenous dose of lidocaine is administered rapidly, seizures can occur. When plasma concentrations of the drug rise slowly above the therapeutic range, as may occur during maintenance therapy, tremor, dysarthria, and altered levels of consciousness are more common. Nyctagmus is an early sign of lidocaine toxicity.

**Clinical Pharmacokinetics**

Lidocaine is well absorbed but undergoes extensive though variable first-pass hepatic metabolism; thus, oral use of the drug is inappropriate. In theory, therapeutic plasma concentrations of lidocaine may be maintained by intermittent intramuscular administration, but the intravenous route is preferred (Table 30–5). Lidocaine’s metabolites, GX and monoethyl GX, are less potent as Na$^+$ channel blockers than the parent drug. GX and lidocaine appear to compete for access to the Na$^+$ channel, suggesting that with infusions during which GX accumulates, lidocaine’s efficacy may be diminished. With infusions lasting longer than 24 h, the clearance of lidocaine falls—an effect that may result from competition between parent drug and metabolites for access to hepatic drug-metabolizing enzymes. Plasma concentrations of lidocaine decline biexponentially after a single intravenous dose, indicating that a multicompartment model is necessary to analyze lidocaine disposition. The initial drop in plasma lidocaine following intravenous administration occurs rapidly, with a $t_{1/2}$ of about 8 min, and represents distribution from the central compartment to peripheral tissues. The terminal elimination $t_{1/2}$ of about 2 h represents drug elimination by hepatic metabolism. Lidocaine’s efficacy depends on maintenance of therapeutic plasma concentrations in the central compartment. Therefore, the administration of a single bolus dose of lidocaine can result in transient arrhythmia suppression that dissipates rapidly as the drug is distributed and concentrations in the central compartment fall. To avoid this distribution-related loss of efficacy, a loading regimen of 3 to 4 mg/kg over 20–30 min is used (e.g., an initial 100 mg followed by 50 mg every 8 min for three doses). Subsequently, stable concentrations can be maintained in plasma with an infusion of 1 to 4 mg/min, which replaces drug removed by hepatic metabolism. The time to steady-state lidocaine concentrations is approximately 8–10 h. If the maintenance infusion rate is too low, arrhythmias may recur hours after the institution of apparently successful therapy. On the other hand, if the rate is too high, toxicity may result. In either case, routine measurement of plasma lidocaine concentration at the time of expected steady state is useful in adjusting maintenance infusion rate.

In heart failure, the central volume of distribution is decreased, so the total loading dose should be decreased. Because lidocaine clearance also is decreased, the rate of the maintenance infusion should be decreased. Lidocaine clearance also is reduced in hepatic disease, during treatment with cimetidine or β blockers, and during prolonged infusions. Frequent measurement of plasma lidocaine concentration and dose adjustment to ensure that plasma concentrations remain within the therapeutic range (1.5 to 5 μg/mL) are necessary to minimize toxicity in these settings. Lidocaine is bound to the acute-phase reactant α1-acid glycoprotein. Diseases such as acute myocardial infarction are associated with increases in α1-acid glycoprotein and protein binding and hence a decreased proportion of free drug. These findings may explain why some patients require and tolerate higher-than-usual total plasma lidocaine concentrations to maintain antiarrhythmic efficacy.

**Magnesium**

The intravenous administration of 1 to 2 g MgSO₄ reportedly is effective in preventing recurrent episodes of torsades de pointes, even if the serum Mg$^{2+}$ concentration is normal (Brugada, 2000). However, controlled studies of this effect have not been performed. The mechanism of action is unknown because the QT interval is not shortened; an effect on the inward current,
possibly a Ca²⁺ current, responsible for the triggered upstroke arising from EADs (black arrow, Figure 30–6B) is possible. Intravenous Mg²⁺ also has been used successfully in arrhythmias related to digitalis intoxication. Large placebo-controlled trials of intravenous Mg²⁺ to improve outcome in acute myocardial infarction have yielded conflicting results (ISIS-4 Collaborative Group, 1995; Woods and Fletcher, 1994). While oral Mg²⁺ supplements may be useful in preventing hypomagnesemia, there is no evidence that chronic Mg²⁺ ingestion exerts a direct antiarrhythmic action.

**Mexiletine**

Mexiletine is an analogue of lidocaine that has been modified to reduce first-pass hepatic metabolism and permit chronic oral therapy. The electrophysiological actions are similar to those of lidocaine. Tremor and nausea, the major dose-related adverse effects, can be minimized by taking the drugs with food.

Mexiletine undergoes hepatic metabolism, which is inducible by drugs such as phenytoin. Mexiletine is approved for treating ventricular arrhythmias; combinations of mexiletine with quinidine or sotalol may increase efficacy while reducing adverse effects. In vitro studies and clinical case series have suggested a role for mexiletine (or flecainide; see previous discussion) in correcting the aberrant late inward Na⁺ current in type 3 congenital LQTS (Napolitano et al., 2006).

**Procainamide**

Procainamide is an analogue of the local anesthetic procaine (see Figure 22–1). It exerts electrophysiological effects similar to those of quinidine but lacks quinidine’s vagolytic and a adrenergic blocking activity. Procainamide is better tolerated than quinidine when given intravenously. Loading and maintenance intravenous infusions are used in the acute therapy of many supraventricular and ventricular arrhythmias. However, long-term oral treatment is poorly tolerated and often is stopped owing to adverse effects.

**Pharmacological Effects**

Procainamide is a blocker of open Na⁺ channels with an intermediate time constant from block. It also prolongs cardiac action potentials in most tissues, probably by blocking outward K⁺ currents. Procainamide decreases automaticity, increases refractory periods, and slows conduction. The major metabolite, N-acetyl procainamide, lacks the Na⁺ channel-blocking activity of the parent drug but is equipotent in prolonging action potentials.

Because the plasma concentrations of N-acetyl procainamide often exceed those of procainamide, increased refactoriness and QT prolongation during chronic procainamide therapy may be partly attributable to the metabolite. However, it is the parent drug that slows conduction and produces QRS interval prolongation. Although hypotension may occur at high plasma concentrations, this effect usually is attributable to ganglionic blockade rather than to any negative inotropic effect, which is minimal.

**Adverse Effects**

Hypotension and marked slowing of conduction are major adverse effects of high concentrations (>10 μg/mL) of procainamide, especially during intravenous use. Dose-related nausea is frequent during oral therapy and may be attributable in part to high plasma concentrations of N-acetyl procainamide. Torsades de pointes can occur, particularly when cardiac plasma concentrations of N-acetyl procainamide rise to greater than 30 μg/mL. Procainamide produces potentially fatal bone marrow aplasia in 0.2% of patients; the mechanism is not known, but high plasma drug concentrations are not suspected.

During long-term therapy, most patients will develop biochemical evidence of the drug-induced lupus syndrome, such as circulating anti-nuclear antibodies. Therapy need not be interrupted merely because of the presence of antinuclear antibodies. However, 25%–50% of patients eventually develop symptoms of the lupus syndrome; common early symptoms are rash and small-joint arthralgias. Other symptoms of lupus, including pericarditis with tamponade, can occur, although renal involvement is unusual. The lupus-like symptoms resolve on cessation of therapy or during treatment with N-acetyl procainamide (see discussion that follows).

**Clinical Pharmacokinetics**

Procainamide is eliminated rapidly (t₁/₂ ~ 3–4 h) by both renal excretion of unchanged drug and hepatic metabolism. The major pathway for hepatic metabolism is conjugation by N-acetyl transferase, whose activity is determined genetically, to form N-acetyl procainamide. N-Acetyl procainamide is eliminated by renal excretion (t₁/₂ ~ 6–10 h) and is not significantly converted back to procainamide. Because of the relatively rapid elimination rates of both the parent drug and its major metabolite, oral procainamide usually is administered as a slow-release formulation. In patients with renal failure, procainamide or N-acetyl procainamide can accumulate to potentially toxic plasma concentrations. Reduction of procainamide dose and dosing frequency and monitoring of plasma concentrations of both compounds are required in this situation. Because the parent drug and metabolite exert different pharmacological effects, the past practice of using the sum of their concentrations to guide therapy is inappropriate.

In individuals who are “slow acetylators,” the procainamide-induced lupus syndrome develops more often and earlier during treatment than among rapid acetylators. In addition, the symptoms of procainamide-induced lupus resolve during treatment with N-acetyl procainamide. Both these findings support results of in vitro studies suggesting that it is chronic exposure to the parent drug (or an oxidative metabolite) that results in the lupus syndrome; these findings also provided one rationale for the further development of N-acetyl procainamide and its analogues as antiarrhythmic agents (Roden, 1993).

**Propafenone**

Propafenone is a Na⁺ channel blocker with a relatively slow time constant for recovery from block (Funck-Brentano et al., 1990). Some data suggest that, like flecainide, propafenone also blocks K⁺ channels. Its major electrophysiological effect is to slow conduction in fast-response tissues. The drug is prescribed as a racemate; while the enantiomers do not differ in their Na⁺ channel-blocking properties, S-(+)-propafenone is a β adrenergic receptor antagonist in vitro and in some patients. Propafenone prolongs PR and QRS durations. Chronic therapy with oral propafenone is used to maintain sinus rhythm in patients with supraventricular tachycardias, including atrial fibrillation; like other Na⁺ channel blockers, it also can be used in ventricular arrhythmias, but with only modest efficacy. R-(−)-propafenone blocks ByR2 channels and may be an alternative to flecainide in CPVT (Hwang et al, 2011).

**Adverse Effects**

Adverse effects during propafenone therapy include acceleration of ventricular response in patients with atrial flutter, increased frequency or severity of episodes of reentrant ventricular tachycardia, exacerbation of heart failure, and the adverse effects of β adrenergic blockade, such as sinus bradycardia and bronchospasm (see previous discussion and Chapter 12).

**Clinical Pharmacokinetics**

Propafenone is well absorbed and is eliminated primarily by CYP2D6-mediated hepatic metabolism (see Chapter 6). In most subjects (“extensive metabolizers”), propafenone undergoes extensive first-pass hepatic metabolism to 5-hydroxy propafenone, a metabolite equipotent to propafenone as a Na⁺ channel blocker but much less potent as a β adrenergic receptor antagonist. A second metabolite, N-desalkyl propafenone, is formed by non-CYP2D6–mediated metabolism and is a less-potent blocker of Na⁺ channels and β adrenergic receptors. CYP2D6-mediated metabolism of propafenone is saturable, so small increases in dose can increase plasma propafenone concentration disproportionately. In “poor metabolizer” subjects, in whom CYP2D6 activity is low or absent, first-pass hepatic metabolism is much less than in extensive metabolizers, and plasma propafenone concentrations will be much higher after an equal dose. The incidence of adverse effects during propafenone therapy is significantly higher in poor metabolizers.
CYP2D6 activity can be inhibited markedly by a number of drugs, including quinidine and fluoxetine. In extensive metabolizer subjects receiving such drugs or in poor metabolizer subjects, plasma propafenone concentrations of more than 1 μg/mL are associated with clinical effects of β adrenergic receptor blockade, such as reduction of exercise heart rate. It is recommended that dosage in patients with moderate-to-severe liver disease should be reduced to approximately 20%–30% of the usual dose, with careful monitoring. It is not known if propafenone doses must be decreased in patients with renal disease. A slow-release formulation allows twice-daily dosing.

**Quinidine**

As early as the 18th century, the bark of the cinchona plant was used to treat "rebellious palpitations" (Levy and Azoulay, 1994). Studies in the early 20th century identified quinidine, a diastereomer of the antimalarial quinine, as the most potent of the antiarrhythmic substances extracted from the cinchona plant, and by the 1920s, quinidine was used as an antiarrhythmic agent. Quinidine is used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or VF (Grace and Camm, 1998). Quinidine may be especially useful in preventing recurrent VF in unusual congenital arrhythmias syndromes such as Brugada syndrome or short QT syndrome (Inama et al., 2010; Viskin et al., 2013).

![Quinidine molecular structure](attachment:quinidine.png)

**Pharmacological Effects**

Quinidine blocks Na⁺ current and multiple cardiac K⁺ currents. It is an open-state blocker of Na⁺ channels, with a τ_recov in the intermediate (~3-sec) range; as a consequence, QRS duration increases modestly, usually by 10%–20%, at therapeutic dosages. At therapeutic concentrations, quinidine commonly prolongs the QT interval up to 25%, but the effect is highly variable. At concentrations as low as 1 μM, quinidine blocks Na⁺ current and the rapid component of delayed rectifier (IKₛ); higher concentrations block the slow component of delayed rectifier, inward rectifier, transient outward current, and L-type Ca²⁺ current.

Quinidine's Na⁺ channel–blocking properties result in an increased threshold for excitability and decreased automaticity. As a consequence of its K⁺ channel–blocking actions, quinidine prolongs action potentials in most cardiac cells, most prominently at slow heart rates. In some cells, such as midmyocardial cells and Purkinje cells, quinidine consistently elicits EADs at slow heart rates, particularly when [K]ₒ is low (Priori et al., 1999). Quinidine prolongs refractoriness in most tissues, probably as a result of both prolongation of action potential duration and Na⁺ channel blockade.

In intact animals and humans, quinidine also produces a adrenergic receptor blockade and vagal inhibition. Thus, the intravenous use of quinidine is associated with marked hypotension and sinus tachycardia. Quinidine's vagolytic effects tend to inhibit its direct depressant effect on AV nodal conduction, so the effect of drug on the PR interval is variable. Moreover, quinidine's vagolytic effect can result in increased AV nodal transmission of atrial tachycardias such as atrial flutter (Table 30–1).

**Adverse Effects**

**Noncardiac.** Diarrhea is the most common adverse effect during quinidine therapy, occurring in 30%–50% of patients; the mechanism is not known. Diarrhea usually occurs within the first several days of quinidine therapy but can occur later. Diarrhea-induced hypokalemia may potentiate torsades de pointes due to quinidine.

A number of immunological reactions can occur during quinidine therapy. The most common is thrombocytopenia, which can be severe but which resolves rapidly with discontinuation of the drug. Hepatitis, bone marrow depression, and lupus syndrome occur rarely. None of these effects is related to elevated plasma quinidine concentrations.

Quinidine also can produce cinchonism, a syndrome that includes headache and tinnitus. In contrast to other adverse responses to quinidine therapy, cinchonism usually is related to elevated plasma quinidine concentrations and can be managed by dose reduction.

**Cardiac.** Of patients receiving quinidine therapy, 2%–8% will develop marked QT interval prolongation and torsades de pointes. In contrast to effects of sotalol, N-acetyl procainamide, and many other drugs, quinidine-associated torsades de pointes generally occurs at therapeutic or even subtherapeutic plasma concentrations. The reasons for individual susceptibility to this adverse effect are not known.

At high plasma concentrations of quinidine, marked Na⁺ channel block can occur, with resulting ventricular tachycardia. This adverse effect occurs when very high doses of quinidine are used to try to convert atrial fibrillation to normal rhythm; this aggressive approach to quinidine dosing has been abandoned, and quinidine-induced ventricular tachycardia is unusual.

Quinidine can exacerbate heart failure or conduction system disease. However, in most patients with congestive heart failure, quinidine is well tolerated, perhaps because of its vasodilating actions.

**Clinical Pharmacokinetics**

Quinidine is well absorbed and is 80% bound to plasma proteins, including albumin and, like lidocaine, the acute-phase reactant α₁-acid glycoprotein. As with lidocaine, greater-than-usual doses (and total plasma quinidine concentrations) may be required to maintain therapeutic concentrations of free quinidine in high-stress states such as acute myocardial infarction. Quinidine undergoes extensive hepatic oxidative metabolism, and approximately 20% is excreted unchanged by the kidneys. One metabolite, 3-hydroxyquinidine, is nearly as potent as quinidine in blocking cardiac Na⁺ channels and prolonging cardiac action potentials. Concentrations of unbound 3-hydroxyquinidine equal to or exceeding those of quinidine, and their plasma concentrations are lower; thus, they are unlikely to contribute significantly to the clinical effects of quinidine.

There is substantial individual variability in the range of dosages required to achieve therapeutic plasma concentrations of 2 to 5 μg/mL. Some of this variability may be assay dependent because not all assays exclude quinidine metabolites. In patients with advanced renal disease or congestive heart failure, quinidine clearance is decreased only modestly. Thus, dosage requirements in these patients are similar to those in other patients.

**Drug Interactions**

Quinidine is a potent inhibitor of CYP2D6. As a result, the administration of quinidine to patients receiving drugs that undergo extensive CYP2D6-mediated metabolism may result in altered drug effects owing to accumulation of parent drug and failure of metabolite formation. For example, inhibition of CYP2D6-mediated metabolism of codeine to its active metabolite morphine results in decreased analgesia. On the other hand, inhibition of CYP2D6-mediated metabolism of propafenone results in elevated plasma propafenone concentrations and increased β adrenergic receptor blockade. Quinidine reduces the clearance of digoxin; inhibition of P-glycoprotein–mediated digoxin transport has been implicated (Fromm et al., 1999). Dextromethorphan, a CYP2D6 substrate that undergoes extensive first-pass bioactivation, has shown promise in treatment of various neurological disorders, notably pseudobulbar affect. A combination of dextromethorphan and very low-dose quinidine (30 mg) inhibits the first-pass metabolism, achieves higher systemic concentrations than monotherapy, and is now approved for use in pseudobulbar affect (Olney and Rosen, 2010).

Quinidine metabolism is induced by drugs such as phenobarbital and phenytoin. In patients receiving these agents, very high doses of quinidine...
may be required to achieve therapeutic concentrations. If therapy with the inducing agent is then stopped, quinidine concentrations may rise to very high levels, and its dosage must be adjusted downward. Cimetidine and verapamil also elevate plasma quinidine concentrations, but these effects usually are modest.

**Sotalol**

*Sotalol* is a nonselective β adrenergic receptor antagonist that also prolongs cardiac action potentials by inhibiting delayed rectifier and possibly other K+ currents (Hohnloser and Woosley, 1994). Sotalol is prescribed as a racemate; the l-enantiomer is a much more potent β adrenergic receptor antagonist than the d-enantiomer, but the two are equipotent as K+ channel blockers. In the U.S., sotalol is approved for use in patients with both ventricular tachyarrhythmias and atrial fibrillation or flutter. Clinical trials suggest that it is at least as effective as most Na+ channel blockers in ventricular arrhythmias.

Sotalol prolongs action potential duration throughout the heart and QT interval on the ECG. It decreases automaticity, slows AV nodal conduction, and prolongs AV refractoriness by blocking both K+ channels and β adrenergic receptors, but it exerts no effect on conduction velocity in fast-response tissue. Sotalol causes EADs and triggered activity in vitro and can cause torsades de pointes, especially when the serum K+ concentration is low. Unlike the situation with quinidine, the incidence of torsades de pointes (1.5%–2% incidence) seems to depend on the dose of sotalol; indeed, torsades de pointes is the major toxicity with sotalol overdose. Occasional cases occur at low dosages, often in patients with renal dysfunction, because sotalol is eliminated by renal excretion of unchanged drug. The other adverse effects of sotalol therapy are those associated with β adrenergic receptor blockade (see previous discussion and Chapter 12).

**Vernakalant**

Vernakalant is an inhibitor of multiple ion channels and prolongs atrial refractory periods without significantly affecting ventricular refractoriness. Intravenous vernakalant has modest efficacy in terminating atrial fibrillation (Roy et al., 2008) and is available for this indication in several European countries, but not the U.S. Consult the 12th edition of this text for more information on this drug.

**Acknowledgment:** Kevin J Simpson and Robert S. Kass contributed to this chapter in the previous edition of this book. We have retained some of their text in the current edition.

### Bibliography

Pulmonary Hypertension is a primary disorder of the pulmonary vasculature and a complication of other cardiopulmonary, vascular, and inflammatory diseases. Based on shared pathophysiological and pathological characteristics as well as response to therapies, PH can be classified into five groups (Simonneau et al., 2013):

1. PAH
2. PH owing to left heart disease
3. PH owing to lung diseases or hypoxia
4. Chronic thromboembolic PH
5. PH with unclear multifactorial mechanisms

Pulmonary Arterial Hypertension

Pulmonary arterial hypertension is a rare, progressive, and fatal disease in which vascular changes in the small arteries and arterioles lead to progressive increases in PVR, resulting in increased PAP (McLaughlin et al., 2009). In patients with PAH, elevated afterload increases stress on the RV, leading to RV dysfunction and hypertrophy, and in some cases right heart failure. Patients present with a range of symptoms, including dyspnea, fatigue, chest pain, and syncope. PH is a complication of many chronic diseases and is estimated to affect as much as 10%–20% of the general population (McLaughlin et al., 2009).

Pulmonary Hypertension Classification

Pulmonary hypertension is a primary disorder of the pulmonary vasculature and a complication of other cardiopulmonary, vascular, and inflammatory diseases. Based on shared pathophysiological and pathological characteristics as well as response to therapies, PH can be classified into five groups (Simonneau et al., 2013):

1. PAH
2. PH owing to left heart disease
3. PH owing to lung diseases or hypoxia
4. Chronic thromboembolic PH
5. PH with unclear multifactorial mechanisms

Mechanisms of Pulmonary Arterial Hypertension

Pulmonary arterial hypertension is thought to arise from pathophysiological changes in the small pulmonary arteries and arterioles. Regardless of the initial etiological trigger, the putative mechanisms contributing to elevated PVR and PAP include the following:

- pulmonary vascular remodeling
- sustained pulmonary vasoconstriction
- in situ thrombosis
- pulmonary vascular wall stiffening

Pulmonary Hypertension Associated With Other Disease States

Other PH groups represent the majority of recognized cases of PH. The presence of PH in these more common diseases portends a much poorer prognosis, often identifying people with multiple comorbidities, late-stage presentations, or more severe disease. While recognition of PH in heart and lung disease carries important prognostic implications, to date there are no approved targeted therapies for PH in these other disease states, with the exception of CTEPH. While surgical pulmonary thromboendarterectomy is the treatment of choice in CTEPH, nonsurgical patients or those with persistent PH following surgery respond to pulmonary vasodilator therapy (Fedullo et al., 2011; Ghofrani et al., 2013).

Routes of Drug Delivery to the Pulmonary Circulation

The pulmonary circulation permits delivery of drugs through multiple routes. The pulmonary circulation runs in series with the systemic circulation, receiving the entire CO in each cardiac cycle. Thus, exposure of pulmonary tissue to drugs is excellent and reliable. Continuous intravenous infusion is used to deliver high concentrations of drugs that exhibit short half-lives to the pulmonary circulation while avoiding first-pass metabolism. Alternatively, drug administration by subcutaneous pump may be used to lower risk of adverse effects. Oral delivery remains a safe, effective, and reliable route for many classes of drugs used to treat PAH. The small pulmonary arteries and precapillary arterioles are also unique in their close proximity to the alveoli and lower airways. Hence, inhalational delivery of therapeutic compounds can directly target the lung vasculature and pulmonary circulation, limit systemic side effects, and preferentially affect well-ventilated parts of the lung to improve ventilation-perfusion matching (see Chapter 40).
Each of these mechanisms (Figure 31–1) can contribute to the development and progression of PAH and forms the basis for drug therapy for this disease. Accordingly, an effective therapy for PAH would (1) cause pulmonary vasodilation; (2) exert antiproliferative or proapoptotic effects on highly proliferative cells in the pulmonary vascular wall (e.g., fibroblasts, myofibroblasts, and smooth muscle cells); (3) prevent or resolve in situ thrombosis in small arteries and precapillary arterioles; (4) exert antifibrotic effects to attenuate extracellular matrix stiffness; and (5) reduce pulmonary vascular wall stiffness due to myogenic tone and cholesterol-associated membrane stiffness (Mandegar et al., 2004; Morrell et al., 2009).

Although the cellular and molecular mechanisms leading to these changes in the pulmonary vasculature are complex, an imbalance of vasoactive mediators, mitogenic and angiogenic factors, and pro- and antiproliferative proteins plays an important role in PAH development. Relative deficiencies of vasodilators (e.g., NO and prostacyclin) deleteriously accompany an excess of vasoconstrictors (e.g., ET-1 and TxA2). NO released by the vascular ECs normally promotes the production of cyclic GMP in the PASMCs, resulting in PASMC relaxation and pulmonary vasodilation. PGI2, also released from the vascular endothelium, promotes the synthesis of cAMP, causing PASMC relaxation and pulmonary vasodilation. In addition, NO and PGI2 both have antiproliferative and anticoagulant effects that inhibit concentric pulmonary vascular wall thickening and in situ thrombosis. ET-1 is a potent vasoconstrictor secreted by ECs, yet exerts vasoconstrictive and proliferative effects on PASMCs. Other vasoactive mediators such as TxA2, HHT, and VIP appear to play a role in the development of PAH, but the therapeutic potential of targeting these substances has not been well established. Table 31–1 summarizes the changes in these vasoactive mediators and the likely contributions of those changes to the development of PAH.

Sustained vasoconstriction and pulmonary vascular remodeling also result from functional and transcriptional changes in membrane receptors and ion channels on the surface of PASMCs. Several GPCRs and TKRs are implicated in the development and progression of PAH. Increased cytosolic 
\[\text{Ca}^{2+}\text{]cyt}\] is an important common pathway by which receptor activation and downstream cellular signaling cascades exert their effects in the pulmonary vasculature. A rise in \[\text{Ca}^{2+}\text{]cyt}\] in PASMCs is a major trigger for PASMC contraction and an important mediator for PASMC proliferation, migration, and vascular remodeling. In addition, ion channels, particularly \[\text{Ca}^{2+}\text{-}	ext{permeable cation channels and K}^+\text{-permeable channels (e.g., KCNA5 and KCNK3) in the plasma membrane of PASMCs, can directly influence}\ [\text{Ca}^{2+}\text{]cyt}\] (Mandegar et al., 2004). Ion channels and transporters, such as VDCCs, ROCs, store-operated \[\text{Ca}^{2+}\text{ channels, and the Na}^+\text{-Ca}^{2+}\text{ exchanger, are implicated in the development of PAH; all are potential therapeutic targets. Downregulation of K}^+\text{-permeable channels in PASMCs leads to membrane depolarization and opening of VDCCs, enhancing Ca}^{2+}\text{ influx, with a consequent increase in}\ [\text{Ca}^{2+}\text{]cyt}\] and further sustained vasoconstriction and vascular remodeling (Kuh et al., 2012).
MODULATION OF PULMONARY, RENAL, AND CARDIOVASCULAR FUNCTION

Goals of treatment include improvement in symptoms, such as dyspnea, fatigue, chest pain, or syncope; improved functional capacity, including 6-min walk distance; and improvement in pulmonary and RV hemodynamics. Oral formulations, either ERA, PDE5 inhibitors, or sGC stimulators, are usually employed as first-line agents due to ease of use. Treatment of the most severe PAH patients generally involves parenteral therapy with epoprostenol or treprostinil, the most potent pulmonary vasodilators, yet controversy exists on the initial treatment of patients with moderate-to-severe functional limitations. Sequential combination therapy with the addition of separate classes of medications is often utilized for severe or progressive disease (Ghofrani and Humbert, 2014). Modest effects with single agents may be enhanced with the use of up-front combinations and could lead to more dramatic improvements in both symptoms and hemodynamics (Sitbon et al., 2014; Galie et al., 2015).

Pulmonary hypertension is a complex disease process often complicating common diseases of the heart and lungs and heralding poor outcomes. Despite this, PAH, and more recently CTEPH, are the two only subtypes of PH with safe and effective pharmacotherapy. Supportive care therapies described in other chapters include volume management with diuretics with safe and effective pharmacotherapy. Supportive care therapies contributing to the development and progression of PAH include sustained vasoconstriction, pulmonary vascular remodeling, in situ thrombosis, and vascular wall stiffening.

Pharmacotherapy for Pulmonary Hypertension

Pharmacotherapy for PH targets the major pathogenic mechanisms of the disease—pulmonary vascular remodeling (e.g., concentric pulmonary vascular thickening and intraluminal obliteration), sustained pulmonary vasoconstriction, in situ thrombosis, and pulmonary vascular wall stiffening—with the goals of attenuating the development and progression of PAH and reversing these pathologic changes in patients with established PAH. Currently available PAH therapeutics are classified based on their cellular and molecular mechanisms (see Humbert and Ghofrani, 2016):

- NO and stimulators of cGMP and PKG signaling
- membrane receptor agonists
- membrane receptor antagonists
- ion channel blockers and openers

Stimulators of cGMP and PKG Signaling

Nitric oxide is synthesized mainly in vascular ECs and diffuses into vascular smooth muscle cells (PASMCs) to activate sGC. Activated sGC generates cGMP, which in turn is inactivated by cyclic nucleotide PDE5 to 5′-GMP (Figure 31–3). cGMP is an important intracellular second messenger that signals through (1) cGMP-dependent PKG, the principal downstream mediator of cGMP, and (2) cyclic nucleotide–gated and hyperpolarization-activated cyclic nucleotide–gated (HCN) channels (Craven and Zagotta, 2006). Increased cellular cGMP exerts relaxant and antiproliferative effects on PASMCs and myofibroblasts through activation of cGMP-gated K+ channels, inhibition of Ca2+-permeable channels (e.g., L-type VDCCs, transient receptor potential cation channels), and attenuation of several specific intracellular signaling cascades that are related to cell proliferation, growth, and migration (cAMP [via activated PKA] has similar effects). The drugs currently available for the treatment of PAH in this category include inhaled NO, stimulators and activators of sGC, and inhibitors of PDE5.

The enzymic catalysts of cGMP formation in tissues are sGC and particulate (plasma membrane) mGC. NO stimulates sGC, while the natriuretic peptides stimulate mGC (see Chapter 3 for information on the structure and mechanisms of activation of these enzymes). The sGC is

The source of cGMP synthesis on which therapeutic agents for PAH rely. In the lung, activation of the cGMP-PKG pathway causes relaxation of smooth muscle, inhibits proliferation of bronchial smooth muscle and vascular smooth muscle cells, and has an antiproliferative effect (and can induce apoptosis) in pulmonary vascular smooth muscle cells and ECs (Figure 31–3).

Nitric Oxide

Nitric oxide is biosynthesized from the terminal nitrogen of l-arginine by the enzyme nitric oxide synthase (see Chapter 3). Endogenous NO levels are reduced in patients with PAH, PH associated with connective tissue disease, COPD, and interstitial lung disease (Girgis et al., 2005; Kawaguchi et al., 2006).

ADME. NO is a soluble gas. Inhaled NO is a gaseous blend of NO and N₂ (0.01% and 99.99%, respectively, for 100 ppm NO). NO must be compressed and stored with an inert gas such as N₂ to minimize the exposure to O₂, decreasing the risk of the accumulation of NO₂. Inhaled NO increases the PaO₂ by preferentially vasodilating better-ventilated lung regions from poorly inflated lung areas (i.e., with low ventilation/perfusion [V/Q] ratios). Inhaled NO is generally administered continuously or with a pulsing device that is rapidly triggered with the onset of inspiration; careful monitoring of response is warranted (Griffiths and Evans, 2005). Inhaled NO is a selective pulmonary vasodilator. Its acute and relatively specific effects on PAP and PVR are due to its route of administration and short half-life (2–6 sec), which is primarily a result of the rapid inactivation of NO by hemoglobin binding and oxidation to nitrite; the nitrite interacts with oxyhemoglobin, leading to the formation of nitrate and met-hemoglobin (Bueno et al., 2013). Nitrate has been identified as the predominant NO metabolite excreted in the urine, accounting for more than 70% of the NO dose inhaled (Ichinose et al., 2004).

Clinical Use. NO can acutely lower PAP and PVR without altering systemic arterial pressure. Inhaled NO is used for the treatment of term and near-term neonates with persistent pulmonary hypertension of the newborn and acute hypoxic respiratory failure (Abman, 2013). Inhaled NO is a selective pulmonary vasodilator. Its acute and relatively specific effects on PAP and PVR are due to its route of administration and short half-life (2–6 sec), which is primarily a result of the rapid inactivation of NO by hemoglobin binding and oxidation to nitrite; the nitrite interacts with oxyhemoglobin, leading to the formation of nitrate and met-hemoglobin (Bueno et al., 2013). Nitrate has been identified as the predominant NO metabolite excreted in the urine, accounting for more than 70% of the NO dose inhaled (Ichinose et al., 2004).
MODULATION OF PULMONARY, RENAL, AND CARDIOVASCULAR FUNCTION

In patients with NO deficiency due to dysfunctional endothelial nitric oxide synthase or arginine insufficiency, activation of sGC increases signaling through the cGMP-PKG pathway and exerts a therapeutic effect (Stasch and Evgenov, 2013). Riociguat, a direct activator of sGC, has recently been approved.

Mechanism of Action. Riociguat is the first-in-class stimulator of sGC. The agent exhibits a dual mode of action; it sensitizes sGC to endogenous NO, and it also directly stimulates sGC independently of NO.

ADME. The drug has excellent oral absorption, and the plasma concentration peaks approximately 1.5 h after oral intake (Stasch and Evgenov, 2013). Food does not affect the bioavailability of riociguat; its volume of distribution is about 30 L. Riociguat is metabolized by CYPs 1A1, 3A, 2C8, and 2J2. The action of CYP1A1 forms the major and active metabolite, M1, which is converted to an inactive N-glucuronide. The terminal elimination half-life is about 12 h in patients with PAH (7 h in healthy subjects) (Stasch and Evgenov, 2013).

Clinical Use. Riociguat at doses up to 2.5 mg given three times daily for 12 weeks increased walking distance and significantly delayed time to clinical worsening for patients with PAH (Ghofrani, 2013). Riociguat was also effective in patients with CTEPH, for whom improvements in walking distance were apparent from week 2 onward (Ghofrani et al., 2013).

Adverse Reactions and Precautions. Concurrent use of riociguat with nitroglycerin or PDE5 inhibitors can cause severe hypotension and syncope (Stasch and Evgenov, 2013). Serious adverse effects include embryo-fetal toxicity, hypotension, and bleeding. Other common adverse reactions include headache, dyspepsia, dizziness, nausea, diarrhea, vomiting, anemia, reflux, constipation, palpitations, nasal congestion, epistaxis, dysphagia, abdominal distension, and peripheral edema (Ghofrani et al., 2013; Ghofrani et al., 2013; Stasch and Evgenov, 2013).

PDE5 Inhibitors

Cyclic nucleotide PDEs comprise a superfamily of enzymes that hydrolyze 3′-5′ cyclic nucleotides to their cognate 5′ monophosphates (Omori and Kotera, 2007). PDE5, an isomorph that is relatively specific for cGMP, is abundant in PASMCs (Kass et al., 2007). The physiological importance of PDE5 in the regulation of smooth muscle tone has been most effectively demonstrated by the successful clinical use of its specific inhibitors in the treatment of erectile dysfunction and PAH (Galilei et al., 2005; Ravipati et al., 2007).

Sildenafil. Mechanism of Action. Sildenafil, which structurally mimics the purine ring of cGMP, is a competitive and selective inhibitor of PDE5. Sildenafil has a relatively high selectivity (>1000-fold) for human PDE5 over other PDEs. By inhibiting cGMP hydrolysis, sildenafil elevates cellular levels of cGMP and augments signaling through the cGMP-PKG pathway, provided guanylyl cyclase is active.

ADME. The drug is rapidly absorbed and reaches a peak plasma concentration 1 h after oral administration. Sildenafil is cleared by the hepatic CYP3A (major route) and CYP2C9 (minor). Sildenafil and its major active metabolite, N-desmethyl sildenafil, have terminal half-lives of about 4 h. Both the parent compound and the major metabolite are highly bound to plasma proteins (96%) (Cockrill and Waxman, 2013). Metabolites are predominantly excreted into the feces (73%–88%) and to a lesser extent into the urine; unmetabolized drug is not detected in urine or feces (Muirhead et al., 2002). Clearance is reduced in the elderly (>65 years), leading to an increase in area-under-the-curve values for the parent drug and the N-desmethyl metabolite.

Clinical Use and Adverse Effects and Precautions. Sildenafil, 5 to 20 mg three times per day improves exercise capacity, functional class, and hemodynamics. In addition to improved exercise capacity and hemodynamic parameters, sildenafil (initiated at 20 mg three times daily, titrated to 40–80 mg three times per day) plus long-term epoprostenol therapy also resulted in delayed time to clinical worsening of PAH in clinical studies.
Dose adjustments for reduced renal and hepatic function are usually not necessary except for severe hepatic and renal impairment (Cockrill and Waxman, 2013). Concomitant administration of potent CYP3A inducers (e.g., bosentan) will generally cause substantial decreases in plasma levels of sildenafil. The mean reduction in the bioavailability of sildenafil (80 mg three times a day) when coadministered with epoprostenol was 28% (Cockrill and Waxman, 2013). CYP3A inhibitors (e.g., protease inhibitors used in HIV therapy, erythromycin, and cimetidine) inhibit sildenafil metabolism, thereby prolonging the t1/2 and elevating blood levels of sildenafil. Consistent with its mechanism of action, potentiation of cGMP signaling, sildenafil and other PDE5 inhibitors potentiate the hypotensive effects of nitrate vasodilators, producing dangerously low blood pressure. Thus, the administration of PDE5 inhibitors to patients receiving organic nitrates is contraindicated. In any event, the patient’s underlying cardiovascular status and concurrent use of hypotensive agents (e.g., nitrate vasodilators, a adrenergic antagonists) must be considered prior to use of this class of drugs.

Headache (16%) and flushing (10%) are the most frequently reported side effects. Patients taking sildenafil or vardenafil may notice a transient blue-green tinting of vision due to inhibition of retinal PDE6, which is involved in phototransduction (see Figure 69-9).

**Other PDE5 Inhibitors.** Vardenafil is structurally similar to sildenafil and a potent inhibitor of PDE5. Although not FDA-approved for PAH in the U.S., its clinical efficacy in PAH appears similar to that of sildenafil (Cockrill and Waxman, 2013). Tadalafil, another PDE5 inhibitor, used for the treatment of PAH, differs structurally from sildenafil and has a longer half-life (Cockrill and Waxman, 2013). See Table 45–2 for comparative pharmacokinetic data of PDE5 inhibitors.

**Prostacyclin Receptor Agonists**

Prostacyclin is mainly synthesized in and released from vascular ECs and exerts relaxant and antiproliferative effects on vascular smooth muscle cells. Similar to NO, endogenous PGI2 is considered an endothelium-derived relaxing factor. Decreased PGI2 synthesis occurs in patients with idiopathic PAH, a finding that provided the rationale for using PGI2 and its analogues for treatment of PAH (Christman et al., 1992).

**Mechanism of Action.** Prostacyclin binds to the IPR in the plasma membrane of PASMCs and activates the Gs-AC-cAMP-PKA pathway (Figure 31–4). PKA continues the signaling cascade by (1) decreasing [Ca2+]i via activating K+ channels (which causes membrane hyperpolarization and repolarization, leading to closure of VDCCs) and (2) inhibiting myosin light chain kinase, thereby causing smooth muscle relaxation and vasodilatation (Olschewski et al., 2004). Activated PKA can also exert an antiproliferative effect on PASMCs by inhibiting the signaling cascades of hedgehog, ERK/p21, and Akt/mTOR. Inhibition of cyclic nucleotide PDEs, mainly PDE3 and PDE4, enhances the cAMP-PKA–mediated relaxant and antiproliferative effects on vascular smooth muscle cells.

**Epoprostenol (Prostacyclin)**

**Clinical Use, Adverse Effects and Precautions.** The first synthetic PGI2, epoprostenol, has dose-dependent inhibitory effects on both SVR and PVR, paired with increases in cardiac output, for patients with PAH (Rubin et al., 1982). Epoprostenol’s short half-life (3–5 min) requires the use of a drug delivery pump system for continuous intravenous infusion to achieve long-term efficacy in the treatment of PAH. In a clinical trial, epoprostenol treatment caused significant improvements in pulmonary hemodynamics, patient symptoms, and survival over a 12-week period (Barst et al., 1996).

Epoprostenol is light and temperature sensitive, although a more recent thermostable formulation is now available that permits its use at room temperature (20°C–25°C). This agent remains a mainstay of PAH treatment, particularly in advanced stages of the disease. Adverse effects of epoprostenol are similar for the entire class of PGI2 analogues and include myalgias and pain in the extremities, jaw pain, nausea, headaches, abdominal discomfort, diarrhea, flushing, dizziness, and systemic hypotension. Side effects are generally dose dependent, and slow titration is required for the drug to be sufficiently tolerated.

---

![Figure 31–4](Brunton_Dili31_p0573-p0584.indd, 578)

**Figure 31–4 Membrane receptor agonists that increase CAMP.** Therapies targeting the IPR, including PGI2, PGI analogues, and selexipag, increase CAMP through stimulation of its production by AC. The vasodilating properties of CAMP are produced through decreased [Ca2+]i, as well as anticoagulant and antiproliferative effects that are both dependent and independent of [Ca2+]i. The antiproliferative effects of CAMP (panel B) are shown through numerous distinct pathways, many of which are currently under investigation as novel therapies.
Treprostinil

Clinical Use. Treprostinil, a PGI₂ analogue with longer half-life than that of epoprostenol, is available for continuous intravenous infusion, subcutaneous infusion, inhalation, and oral delivery. The risk of bacteremia or other catheter-related complications can be reduced by subcutaneous delivery. Subcutaneous treprostinil has similar efficacy to intravenous formulations of epoprostenol and treprostinil (Simonneau et al., 2002). Adverse effects related to delivery into the subcutaneous tissue of the lower abdomen are common, including pain and erythema in a majority of patients; these effects subside over time.

Compared to intravenous treprostinil, the inhaled formulation has more potent pulmonary vasodilating effects, but patients find the dosing scheme complex: Multiple breaths are taken through a nebulizer or inhaler four times a day and slowly titrated up to a maximum of nine breaths four times a day. Inhaled treprostinil has comparable hemodynamic effects to inhaled iloprost with a longer duration of effect in patients with PAH. The most common adverse effect related to inhalation is transient coughing.

Monotherapy with extended-release oral formulations of treprostinil are effective in patients with PAH with moderate functional impairments (Jing et al., 2013). The dose is given twice a day, starting at 0.25 mg and titrating up every 3 days to a maximum of 21 mg twice a day. Serum concentrations at a steady dose of 3.5 mg twice daily are thought to approximate therapeutic levels of intravenous treprostinil. Oral treprostinil fails to show any significant improvement in 6-min walk distance for patients on baseline treatment with either an ERA or PDE5 inhibitor and is therefore not recommended in patients already treated (Tapson et al., 2012).

Iloprost

Clinical Use, Adverse Effects, and Precautions. The first PGI₂ analogue available in an inhaled formulation, iloprost was designed to target the pulmonary vasculature with minimal systemic side effects. Inhalation has potent vasodilative effects on the pulmonary circulation, with less systemic vasodilation than intravenous PGI₂ (Olschewski et al., 1996). The effects of a single inhalation decline to baseline over 60–120 min, and current dosing strategies suggest 6–9 inhalations daily. The dose is generally titrated from 2.5 mg/inhalation to 5 mg after the first 2–4 weeks. Minor side effects common to the PGI₂ class include headache and jaw pain. Side effects specific to the inhaled formulation are cough, although this appears to resolve over time.

Beraprost

The first orally available PGI₂ analogue, beraprost, showed promise in early trials, but long-term trials showed no benefit over 12 months of therapy (Barst et al., 2003). As a result, beraprost is not approved for use in the U.S. or E.U.

Selexipag

Selexipag is an orally active, selective IP receptor antagonist that is chemically distinct and has different kinetic properties compared to other PGI₂ analogues.

ADME. Selexipag is rapidly absorbed and hydrolyzed in the liver (t₁/₂ = 1–2 h) to an active metabolite, ACT-333679 (Kaufmann et al., 2015). The active metabolite has a longer half-life, 10–14 h, allowing twice-daily dosing.

Clinical Use, Adverse Effects, and Precautions. The drug is taken at a starting dose of 200 μg and titrated upward weekly to a maximum dose of 1600 μg twice daily. In phase 3 clinical trials, selexipag reduced the risk of morbidity and mortality in patients with PAH (Simonneau et al., 2012; Sitbon et al., 2015). Selexipag was added to existing pulmonary vasodilator therapy in a majority of patients in the clinical trials for this agent. Adverse effects of selexipag are similar to those of PGI₂ analogues and include headache, jaw pain, nausea, dizziness, flushing, nasopharyngitis, and vomiting. Adverse effects appear to be more common when the drug is taken while fasting and wane over time.
metabolized by hepatic CYPs 2C9 and 3A4 with a t1/2 of about 16 h, that of the active metabolite is 9 h. The activation of ET receptors on ECs mediates vasodilation by increasing production of NO and PGI2, and can inhibit ET-1 production.

**Rationale for Antagonizing ET’s Effects in PAH.** Endothelin 1 is implicated as a contributory factor in idiopathic PAH (Giadi et al., 1993): Plasma ET-1 levels are increased up to 10-fold in patients with PAH and correlated with severity of disease and elevation of right atrial pressure. There are no clinically available specific inhibitors of ECE-1, the rate-limiting step in ET-1 synthesis, but a number of orally effective small molecule antagonists of ET receptors have been developed. Despite the opposing effects of ET and ET receptor activation, pharmacological targeting of specific ET receptors has not led to significantly altered clinical responses compared to dual antagonism (e.g., antagonism of ET-1 binding to both ETa and ETb receptors) in treating PAH.

**Endothelin Receptor Antagonists**

Available ET receptor antagonists (ERAs) are bosentan, macitentan, and ambrisentan.

**Commonalities.** Endothelin antagonists generally share adverse effects. Common side effects of the class include headache, pulmonary edema, and nasal congestion/pharyngitis, with a risk of tricuspid atrophy and infertility. Bosentan and ambrisentan may increase liver transaminases, which should be monitored closely, and the drugs are contraindicated in patients with moderate-to-severe liver disease; the elevation of liver enzymes generally resolves after discontinuation of treatment.

The three available ET antagonists are metabolized by CYP3A4 and to some extent by CYPs 2C9 and 2C19. Repeated bosentan dosing elicits cross tolerance with a t1/2 of 12 h, with the exception of drugs that are also metabolized by these CYPs (contraceptives, warfarin, some statins; induction of CYPs 3A4 and 2C9, reducing exposure to drugs that are metabolized by these CYPs). Likewise, coadministration of bosentan or macitentan with a CYP inducer such as rifampin should be avoided. Inhibitors of these CYPs (e.g., ketoconazole and ritonavir) can increase bosentan and macitentan exposure (O’Callaghan et al., 2011).

The ERAs are potent teratogens and should be used with caution in women of childbearing age. These agents must not be used in pregnant patients. Documentation of a negative pregnancy test prior to initiation of therapy and a clear contraceptive plan are recommended, and fertile women must use two acceptable methods of birth control while taking ET antagonists.

**Bosentan.** Bosentan is a nonpeptide, orally effective, competitive antagonist of ETa and ETb receptors. In patients with PAH with mild-to-severe functional impairment (functional classes II–IV), bosentan improves symptoms, functional capacity, and pulmonary hemodynamic parameters (Rubin et al., 2002). Bosentan is usually started at 62.5 mg twice daily, increasing to 125 mg twice daily after 4 weeks. Bosentan is metabolized by hepatic CYPs 2C9 and 3A4 with a t1/2 of about 5 h, with excretion of metabolites in the bile.

**Macitentan.** Macitentan is an orally active, competitive ETa and ETb receptor antagonist. At a dose of 10 mg daily, macitentan improves the time to disease progression or death in PAH and improves symptoms, functional capacity, and pulmonary hemodynamic measurements (Pulido et al., 2013). The drug is relatively well tolerated and has thus far not been associated with elevation of liver-associated enzymes, but caution is recommended. Macitentan is metabolized by CYPs to an active metabolite; the t1/2 of the parent compound is about 16 h, that of the active metabolite about 48 h, such that the metabolite contributes about 40% of the total pharmacologic activity over time.

**Ambrisentan.** Unlike bosentan and macitentan, ambrisentan is a relatively selective ETa antagonist (approximately 4000 times greater affinity for ETa than ETb). Ambrisentan is initiated at a dose of 5 mg daily and increased to a maximum of 10 mg daily. The t1/2 is 9 h at steady state. Liver-associated enzyme abnormalities are much less common than with bosentan, yet monitoring of liver function tests is still recommended. Elimination is largely via nonrenal pathways that have not been extensively characterized. There is some metabolism by CYPs 3A4 and 2C19, followed by glucuronidation; thus, drug interactions might be expected, although clinically relevant interactions have not been reported.

**Receptor Tyrosine Kinase Inhibitors**

Many growth factors and mitogenic factors are reportedly upregulated in tissues of patients with PAH. Elevations of ET-1, ATP, VIP, PDGF, VEGFs, EGF, fibroblast growth factor, and insulin-like growth factor in lung tissue, vascular smooth muscle cells, and peripheral blood have been assessed in PAH (Budhiraja et al., 2004; Du et al., 2003; Schermuly et al., 2005). These myriad mitogenic factors can activate TKRs, such as PDGF and EGF receptors. Activation of these receptors induces cell proliferation, growth, migration, and contraction in PASMCs, PAECs, and pulmonary vascular fibroblasts. With these actions as a rationale, antagonists of TKRs have been tried as therapeutics for PAH (Moreno-Vinasco et al, 2008; Gomberg-Maitland et al, 2010).

**Imatinib**

Imatinib was initially developed as targeted treatment of chronic myelogenous leukemia by targeting the ABL TKR; the compound is now known to have many other targets, one of which is the PDGF receptor that has been linked to vascular smooth muscle hypertrophy in the development of PAH (Humbert et al., 1998). Imatinib as add-on therapy for refractory PAH has shown efficacy in both case reports and a clinical trial, although serious adverse reactions, particularly subdural hematoma, are of concern (Hooper et al., 2013). Larger clinical trials are needed before imatinib can be used in PAH treatment regimens.

**Calcium Channels and Their Blockers**

An increase in [Ca2+]cyt in PASMCs causes pulmonary vasconstriction and is an important stimulant of proliferation, migration, and vascular remodeling. [Ca2+]cyt in PASMCs can be increased by Ca2+ influx through membrane Ca2+ channels and Ca2+ mobilization through the Ca2+ release channels/IP3 receptors in the SR membrane. [Ca2+]cyt can be decreased in three ways: by Ca2+ extrusion via the Ca2+/Mg2+ ATPase (the Ca2+ pump for ET, than ETa). Ambrisentan is initiated at a dose of 5 mg daily and increased to a maximum of 10 mg daily. The t1/2 is 9 h at steady state. Liver-associated enzyme abnormalities are much less common than with bosentan, yet monitoring of liver function tests is still recommended. Elimination is largely via nonrenal pathways that have not been extensively characterized. There is some metabolism by CYPs 3A4 and 2C19, followed by glucuronidation; thus, drug interactions might be expected, although clinically relevant interactions have not been reported.

**Figure 31–6** Treatment algorithm for use of CCBs in PAH. Vasoreactivity testing is used to identify the minority of patients who may have a substantial benefit from high-dose CCB therapy. These individuals must be monitored closely to ensure a sustained response. Patients without a positive vasodilator response should potentially be started on therapies approved for PAH based on symptoms at presentation. The patients with the most severe disease who fail to respond to therapy may need referral for surgical intervention to treat their disease.
Figure 31–7  Interactions between endothelium and vascular smooth muscle in PAH. A. Balance. In normal pulmonary artery, there is a balance between constrictor and relaxant influences that may be viewed as competition between Ca\(^{2+}\) signaling pathways and cyclic nucleotide signaling pathways in VSM. ET-1 binds to the ET\(_A\) receptor on VSM cells and activates the G\(_q\)-PLC-IP, pathway to increase cytosolic Ca\(^{2+}\); ET-1 may also couple to G\(_i\) to inhibit cAMP production. As VSM cells depolarize, Ca\(^{2+}\) may enter via the L-type Ca\(^{2+}\) channel (Cav1.2) or transient receptor potential cation channel (TRPC6). ECs also produce relaxant factors, PGI\(_2\), and NO. NO stimulates the sGC, causing accumulation of cGMP in VSM cells; PGI\(_2\) binds to the IPR and stimulates cAMP production; elevation of these cyclic nucleotides promotes VSM relaxation (see Figures 31-3, 40-4 and 45-6). B. Imbalance. In PAH, ET-1 production is enhanced, production of PGI\(_2\) and NO is reduced, and the balance is shifted toward constriction and proliferation of VSM. C. Restored balance. In treating PAH, ET\(_A\) receptor antagonists can reduce the constrictor effects of ET-1, and Ca\(^{2+}\) channel antagonists can further reduce Ca\(^{2+}\)-dependent contraction. Exogenous PGI\(_2\) and NO can be supplied to promote vasodilation (relaxation of VSM); the sGC can be activated pharmacologically (riociguat); inhibition of PDE5 can enhance the relaxant effect of elevated cGMP by inhibiting the degradation of cGMP. Thus, these drugs can reduce Ca\(^{2+}\) signaling and enhance cyclic nucleotide signaling, restoring the balance between the forces of contraction/proliferation and relaxation/antiproliferation. Remodeling and deposition of extracellular matrix by adjacent fibroblasts is influenced positively and negatively by the same contractile and relaxant signaling pathways, respectively. Effects of pharmacological agonists are noted by green arrows, effects of antagonists by red T-bars.
in the plasma membrane), export of Ca\(^{2+}\) by the Na\(^+/\)Ca\(^{2+}\) exchanger, and by sequestration of cytosolic Ca\(^{2+}\) into the SR by SR Ca\(^{2+}\)-ATPase. There are three classes of Ca\(^{2+}\)-permeable channels functionally expressed in the plasma membrane of PASMCs: (1) VDCCs, (2) ROCs, and (3) store-operated Ca\(^{2+}\) channels. These are targets in the current therapy of PAH and putative targets for therapeutics of the future.

**Voltage-Gated Ca\(^{2+}\) Channel Blockers**

A rare subset of patients (typically less than 5%–15% of all group I PAH confirmed by right heart catheterization) is considered vasoreactive, which is defined as a significant decrease in mean PAP (>10 mm Hg drop to absolute mean PAP < 40 mm Hg) while preserving cardiac output during the administration of inhaled NO or intravenous injection of PGI\(_2\), or adenosine (Rich and Brundage, 1987). Vasoreactive patients can achieve prolonged survival, sustained functional improvement, and hemodynamic improvement with CCB therapy (Hemnes et al., 2015; Rich and Brundage, 1987). The utility of CCB therapy in patients with vasoreactive PAH was supported by a series of well-designed observational studies (Hemnes et al., 2015; Rich and Brundage, 1987; Sitbon et al., 2005).

**Clinical Use.** Therapy with CCB can be initiated with a low dose of long-acting nifedipine, amlopidine, diltiazem, or verapamil. The dose is then increased to the maximal tolerated dose. Systemic blood pressure, heart rate, and oxygen saturation should be carefully monitored during titration. Sustained-release preparations of nifedipine, verapamil, and diltiazem are available that minimize the adverse effects associated with deterioration of RV function because of their inhibitory effect on VDCC in cardiomyocytes. The pharmacology of CCBs is discussed in detail in Chapter 27.

**Adverse Effects and Precautions.** Adverse effects are common with CCB therapy. Systemic vasodilation may cause hypotension, while pulmonary vasodilation may reduce HPV. Loss or inhibition of HPV can worsen V/Q mismatch and cause hypoxemia. CCBs may also be associated with deterioration of RV function because of their inhibitory effect on VDCC.

**PAH Drugs in Development**

In addition to the PAH drugs in clinical use, there are many repurposed drugs and newly developed drugs that have therapeutic benefits in experimental models of PH. These agents have potential as future therapies for PAH:

- antagonists of SHT\(_{1a}\) receptors and transporters (e.g., LY393558);
- allosteric antagonists of Ca\(^{2+}\)-sensing receptors (e.g., NPS2143 and calhex 231);
- openers or activators of Ca\(^{2+}\)-activated and voltage-gated K\(^+\) channels and ATP-sensitive K\(^+\) channels (e.g., cromakalim);
- inhibitors of the PI3K/Akt1/mTOR signaling cascades (e.g., perifosine, ipatasertib, and rapamycin derivatives sirolimus, temsirolimus, everolimus, deforolimus);
- inhibitors of the Notch signaling pathway (e.g., DAPT and MK-0752);
- VIP;
- blockers of transient receptor potential cation channels (e.g., 2-APB, ML204, aniline-thiazoles);
- extracellular elastase inhibitors (e.g., elafin and sivelestat);
- Rho kinase inhibitors (e.g., fasudil); and
- angiopoietin 1 inhibitors (e.g., trebananib).

Some of these drugs are already in phase 3 clinical trials; others are still in preclinical development.

**A Pharmacologist’s View of Signal Integration in PAH**

As noted, an imbalance of vasoactive mediators, mitogenic and angiogenic factors, and pro- and antiapoptotic proteins plays an important role in PAH development. The pharmacological agents employed in PAH are focused on restoring the balance between contraction and proliferation on the one hand and relaxation and antiproliferation on the other, as summarized in Figure 31–7.

### Endothelin Receptor Antagonists: Oral administration, teratogenic

- **Bosentan**
  - First-line therapy for moderate PAH (functional class II-III)
  - Monitor liver function and hemoglobin levels
  - Metabolized by CYP2C9 and CYP3A4
  - Side effects: liver impairment, palpitations, itching, edema, anemia, respiratory infections
- **Ambrisentan**
  - First-line therapy for moderate PAH (functional class II-III)
  - Side effects: edema, nasal congestion, constipation, flushing, palpitations, abdominal pain
  - Cyclosporin coadministration increases drug levels
  - Low risk for liver toxicity
- **Macitentan**
  - First-line therapy for moderate PAH (functional class II-III)
  - Metabolized by CYP3A4
  - Side effects include nasopharyngitis, headache, anemia
  - Liver function and hemoglobin testing recommended prior to therapy

### L-type Ca²⁺ Channel Blockers

- **Nifedipine** (long acting)
  - Amlopidine
  - Diltiazem
  - Use only in PAH patients with positive vasodilator testing
  - Oral administration
  - Side effects include edema, fatigue, hypotension
  - Diltiazem: significant negative chronotropic and inotropic effects; avoid in bradyacardia

### Bibliography

Kawaguchi Y, et al. NOS2 polymorphisms associated with the susceptibility to pulmonary arterial hypertension with systemic
Blood must remain fluid within the vasculature and yet clot quickly when exposed to subendothelial surfaces at sites of vascular injury. Under normal circumstances, a delicate balance between coagulation and fibrinolysis prevents both thrombosis and hemorrhage. Alteration of this balance in favor of coagulation results in thrombosis. Thrombi, composed of platelet aggregates, fibrin, and trapped red blood cells, can form in arteries or veins. Antithrombotic drugs used to treat thrombosis include antiplatelet drugs, which inhibit platelet activation or aggregation; anticoagulants, which attenuate fibrin formation; and fibrinolytic agents, which degrade fibrin. All antithrombotic drugs increase the risk of bleeding.

This chapter reviews the agents commonly used for controlling blood fluidity, including

- Parenteral anticoagulant heparin and its derivatives, which activate antithrombin, a natural inhibitor of coagulant proteases;
- the parenteral anticoagulant heparin and its derivatives, which activate antithrombin, a natural inhibitor of coagulant proteases;
- the parenterally administered anticoagulants, which block multiple steps in the coagulation cascade;
- the direct oral anticoagulants, which inhibit factor Xa or thrombin;
- fibrinolytic agents, which degrade fibrin;
- antithrombotic drugs used to treat thrombosis include antiplatelet drugs, which inhibit platelet activation or aggregation; anticoagulants, which attenuate fibrin formation; and fibrinolytic agents, which degrade fibrin. All antithrombotic drugs increase the risk of bleeding.

Conversion of Fibrinogen to Fibrin
Fibrinogen, a 340,000-Da protein, is a dimer, each half of which consists of three pairs of polypeptide chains (designated Aα, Bβ, and γ). Disulfide bonds covalently link the chains and the two halves of the molecule. Thrombin converts fibrinogen to fibrin monomers by releasing fibrinopeptide A (a 16–amino acid fragment) and fibrinopeptide B (a 14–amino acid fragment) from the amino termini of the Aα and Bβ chains, respectively.
residues bind Ca2+ and are essential for the coagulant activities of these and contains the active site of the proteases. In addition, 9–12 Glu residues at their amino terminals, which endows them with the capacity of activation only occurs when prothrombin and factor Xa contain Gla residues at their amino terminals, which endows them with the capacity to bind calcium and interact with the anionic phospholipid surface. Removal of the fibrinopeptides creates new amino termini, which form knobs that fit into preformed holes on other fibrin monomers to form a fibrin gel, which is the end point of in vitro tests of coagulation (see Coagulation In Vitro). Initially, the fibrin monomers are bound to each other noncovalently. Subsequently, factor XIII, a transglutaminase that is activated by thrombin, catalyzes interchain covalent cross-links between adjacent fibrin monomers, which strengthen the clot.

**Structure of Coagulation Factors**

In addition to factor XIII, the coagulation factors include factors II (prothrombin), VII, IX, X, XI, XII, high-molecular-weight kininogen and prekallikrein. A stretch of about 200 amino acid residues at the carboxy termini of each of thesezymogens exhibits homology to trypsin and contains the active site of the proteases. In addition, 9–12 Glu residues near the amino termini of factors II, VII, IX, and X are converted to Gla residues in a vitamin K–dependent posttranslational step. The Gla residues bind Ca2+ and are essential for the coagulant activities of these proteins by enabling their interaction with the anionic phospholipid membrane of activated platelets.

**Nonenzymatic Protein Cofactors**

TF, factor V, and factor VIII are critical cofactors in coagulation. A nonenzymatic lipoprotein cofactor, TF is not normally present on blood-contacting cells. TF is constitutively expressed on the surface of subendothelial smooth muscle cells and fibroblasts, which are exposed when the vessel wall is damaged. TF binds factor VIIa and enhances its catalytic efficiency. The TF/factor VIIa complex initiates coagulation by activating factors IX and X.

**Factor VIII and Factor V Are Procofactors**

Factor VIII circulates in plasma bound to von Willebrand factor, which serves to stabilize it. Factor V circulates in plasma, is stored in platelets in a partially activated form, and is released when platelets are activated. Thrombin releases von Willebrand factor from factor VIII and activates factors V and VIII to yield factor Va and VIIIa, respectively. Once activated, the cofactors bind to the surface of activated platelets and serve as receptors; factor VIIIa serves as the receptor for factor IXa, while factor Va serves as the receptor for factor Xa. In addition to binding factors IXa and Xa, factors VIIIa and Va bind their substrates, factors X and prothrombin (factor II), respectively.

**Activation of Prothrombin**

By cleaving two peptide bonds on prothrombin, factor Xa converts it to thrombin. In the presence of factor Va, a negatively charged phospholipid surface, and Ca2+ (the so-called prothrombinase complex), factor Xa activates prothrombin with 104-fold greater efficiency. This maximal rate of activation only occurs when prothrombin and factor Xa contain Gla residues at their amino terminals, which endows them with the capacity to bind calcium and interact with the anionic phospholipid surface.

**Initiation of Coagulation**

TF exposed at sites of vessel wall injury initiates coagulation via the extrinsic pathway. The small amount of factor VIIa circulating in plasma binds subendothelial TF and the TF–factor VIIa complex, then activates factors X and IX (see Figure 32–2). When bound to TF in the presence of anionic phospholipids and Ca2+ (extrinsic tenase), factor VIIa activity is increased 30,000-fold over that of factor VIIa alone.

The intrinsic pathway is initiated in vitro when factor XII, prekallikrein, and high-molecular-weight kininogen interact with kaolin, glass, or another negatively charged surface to generate small amounts of factor XIIa. Factor XIIa can be activated in vivo by contact of the blood with medical devices, such as mechanical heart valves or extracorporeal circuits, or by cell-free DNA, neutrophil extracellular traps, which are web-like structures composed of DNA and histones extruded from activated neutrophils, or inorganic polyphosphates released from activated platelets.

Factor XIIa activates factor XI and the resultant factor Xla, then activates factor IX. Factor IXa activates factor X in a reaction accelerated by factor VIIIa, anionic phospholipids, and Ca2+–. Optimal thrombin generation depends on the formation of this factor IXa complex (intrinsic tenase) because it activates factor X more efficiently than the TF–factor VIIa complex.

Activation of factor XII is not essential for hemostasis, as evidenced by the fact that patients deficient in factor XII, prekallikrein, or high-molecular-weight kininogen do not have excessive bleeding. Factor XI deficiency is associated with a variable and usually mild bleeding disorder. In contrast, congenital deficiency of factor VIII or IX results in hemophilia A or B, respectively, and is associated with spontaneous bleeding, which can be fatal.

**Fibrinolysis**

The fibrinolytic pathway is summarized in Figure 32–3. The fibrinolytic system dissolves intravascular fibrin through the action of plasmin. To initiate fibrinolysis, plasminogen activators convert single-chain plasminogen, an inactive precursor, into two-chain plasmin by cleavage of a specific peptide bond. There are two distinct plasminogen activators: t-PA and u-PA, which is also known as urokinase. Although both activators are synthesized by endothelial cells, t-PA predominates under most conditions and drives intravascular fibrinolysis, while synthesis of u-PA mainly...
occurs in response to inflammatory stimuli and promotes extravascular fibrinolysis.

The fibrinolytic system is regulated such that unwanted fibrin thrombi are removed, while fibrin in wounds is preserved to maintain hemostasis. t-PA is released from endothelial cells in response to various stimuli. Released t-PA is rapidly cleared from blood or inhibited by PAI-1 and, to a lesser extent, by PAI-2. Therefore, t-PA exerts little effect on circulating plasminogen in the absence of fibrin, and circulating α2-antiplasmin rapidly inhibits any plasmin that is generated. The catalytic efficiency of t-PA activation of plasminogen increases more than 300-fold in the presence of fibrin, which promotes plasmin generation on its surface.

Plasminogen and plasmin bind to lysine residues on fibrin via five loop-like regions near their amino termini, which are known as kringles. To inactivate plasmin, α2-antiplasmin binds to the first of these kringles domains and then blocks the active site of plasmin. Because the kringles domains are occupied when plasmin binds to fibrin, plasmin on the fibrin surface is protected from inhibition by α2-antiplasmin and can digest the fibrin. Once the fibrin clot undergoes degradation, α2-antiplasmin rapidly inhibits any plasmin that escapes from this local milieu. To prevent premature clot lysis, factor XIIIa mediates covalent cross-linking of small amounts of α2-antiplasmin onto fibrin.

When thrombi occlude major arteries or veins, therapeutic doses of plasminogen activators are sometimes administered to rapidly degrade the fibrin and restore blood flow. In high doses, these plasminogen activators promote the generation of so much plasmin that the inhibitory controls are overwhelmed. Plasmin is a relatively nonspecific protease; in addition to degrading fibrin, it degrades several coagulation factors. Reduction in the levels of these coagulation proteins impairs the capacity for thrombin generation, which can contribute to bleeding. In addition, unopposed plasmin tends to dissolve fibrin in hemostatic plugs as well as

---

**Figure 32–1  Platelet adhesion and aggregation.** GPIVI and GPIb are platelet receptors that bind to collagen and vWF, causing platelets to adhere to the subendothelium of a damaged blood vessel. PAR-1 and PAR-4 are PARs that respond to thrombin (IIa); P2Y1 and P2Y12 are receptors for ADP; when stimulated by agonists, these receptors activate the fibrinogen-binding protein GPIb/IIIa and COX-1 to promote platelet aggregation and secretion. TxA2 is the major product of COX-1 involved in platelet activation. Prostacyclin (PGI2), synthesized by endothelial cells, inhibits platelet activation.

---

**Figure 32–2  Major reactions of blood coagulation.** Shown are interactions among proteins of the “extrinsic” (TF and factor VII), “intrinsic” (factors IX and VIII), and “common” (factors X, V, and II) coagulation pathways that are important in vivo. Boxes enclose the coagulation factor zymogens (indicated by Roman numerals); the rounded boxes represent the active proteases. Activated coagulation factors are followed by the letter a: IIa, prothrombin; IXa, thrombin.
that in pathological thrombi, a phenomenon that also increases the risk of bleeding. Therefore, fibrinolytic drugs can produce hemorrhage as their major side effect.

Coagulation In Vitro

Whole blood normally clots in 4–8 min when placed in a glass tube. Under these conditions, contact of the blood with glass activates factor XII, thereby initiating coagulation via the intrinsic pathway. Clotting is prevented if a chelating agent such as EDTA or citrate is added to then dissociates from EPCR, and, in combination with protein S, its non-thrombin-thrombomodulin complex for activation. Activated protein C terminal domain. Protein C binds to EPCR, which presents it to the lipoprotein fraction of plasma or bound to endothelial cell surface. Thrombosis is prevented by several regulatory mechanisms that require healthy vascular endothelium. Nitric oxide and prostacyclin synthesized by endothelial cells inhibit platelet activation (see Chapter 37).

Natural Anticoagulant Mechanisms

Platelet activation and coagulation do not normally occur within an intact blood vessel. Thrombosis is prevented by several regulatory mechanisms that require healthy vascular endothelium. Nitric oxide and prostacyclin synthesized by endothelial cells inhibit platelet activation (see Chapter 37).

Antithrombin is a plasma protein that inhibits coagulation enzymes of the extrinsic, intrinsic, and common pathways. Heparan sulfate proteoglycans synthesized by endothelial cells enhance the activity of antithrombin by about 1000-fold. Another regulatory system involves protein C, a plasma zymogen that is homologous to factors II, VII, IX, and X; its activity depends on the binding of Ca\(^{2+}\) to Gla residues within its amino terminal domain. Protein C binds to EPCR, which presents it to the thrombin-thrombomodulin complex for activation. Activated protein C then dissociates from EPCR, and, in combination with protein S, its non-enzymatic Gla-containing cofactor, activated protein C degrades factors Va and VIIIa. Without these activated cofactors, the rates of activation of prothrombin and factor X are greatly diminished, and thrombin generation is attenuated. Congenital or acquired deficiency of protein C or protein S is associated with an increased risk of venous thrombosis.

Tissue factor pathway inhibitor is a natural anticoagulant found in the lipoprotein fraction of plasma or bound to endothelial cell surface. TFPI first binds and inhibits factor Xa, and this binary complex then inhibits factor VIIa bound to TF. By this mechanism, factor Xa regulates its own generation.

Parenteral Anticoagulants: Heparin, LMWHs, Fondaparinux

Heparin and Its Standardization

Heparin, a glycosaminoglycan found in the secretory granules of mast cells, is synthesized from UDP-sugar precursors as a polymer of alternating d-glucuronic acid and N-acetyl-d-glucosamine residues. Heparin is commonly extracted from porcine intestinal mucosa, which is rich in mast cells, and preparations may contain small amounts of other glycosaminoglycans. Various commercial heparin preparations have similar biological activity (~150 USP units/mg). A USP unit reflects the quantity of heparin that prevents 1 mL of citrated sheep plasma from clotting for 1 h after calcium addition. European manufacturers measure potency with an anti-factor Xa assay. To determine heparin potency, residual factor Xa activity in the sample is compared with that detected in controls containing known concentrations of an international heparin standard. When assessed this way, heparin potency is expressed in international units per milligram. Effective October 1, 2009, the new USP unit dose was harmonized with the international unit dose. As a result, the new USP unit dose is about 10% less potent than the old one, which results in a requirement for somewhat higher heparin doses to achieve the same level of anticoagulation.

Heparin Derivatives

Derivatives of heparin in current use include LMWH and fondaparinux (see their comparison in Table 32–1).

Mechanism of Action.

Heparin, LMWHs, and fondaparinux have no intrinsic anticoagulant activity; rather, these agents bind to antithrombin and accelerate the rate at which it inhibits various coagulation proteases. Synthesized in the liver, antithrombin circulates in plasma at an approximate concentration of 2.5 μM. Antithrombin inhibits activated coagulation factors, particularly thrombin and factor Xa, by serving as a “suicide substrate.” Thus, inhibition occurs when the protease attacks a specific Arg–Ser peptide bond in the reactive center loop of antithrombin and becomes trapped as a stable 1:1 complex. Heparin binds to antithrombin via a specific pentasaccharide sequence that contains a 3-O-sulfated glucosamine residue (Figure 32–4).

Pentasaccharide binding to antithrombin induces a conformational change in antithrombin that renders its reactive site more accessible to the target protease (Figure 32–5). This conformational change accelerates the rate of factor Xa inhibition by at least two orders of magnitude but has no effect on the rate of thrombin inhibition. To enhance the rate of thrombin...
inhibition by antithrombin, heparin serves as a catalytic template to which both the inhibitor and the protease bind. Only heparin molecules composed of 18 or more saccharide units (molecular weight > 5400) are of sufficient length to bridge antithrombin and thrombin together. Consequently, by definition, heparin catalyzes the rates of factor Xa and thrombin inhibition to a similar extent, as expressed by an anti–factor Xa to anti–factor IIa (thrombin) ratio of 1:1 (Figure 32–5A). In contrast, at least half of LMWH molecules (mean molecular weight of 5000, which corresponds with about 17 saccharide units) are too short to provide this bridging function and have no effect on the rate of thrombin inhibition by antithrombin (Figure 32–5B). Because these shorter molecules still induce the conformational change in antithrombin that accelerates inhibition of factor Xa, LMWH has greater anti–factor Xa activity than anti–factor IIa activity, and the ratio ranges from 3:1 to 2:1 depending on the preparation. Fondaparinux, a synthetic analogue of the pentasaccharide sequence in heparin or LMWH that mediates their interaction with antithrombin, has only anti–factor Xa activity because it is too short to bridge antithrombin to thrombin (Figure 32–5C).

Heparin, LMWH, and fondaparinux act in a catalytic fashion. After binding to antithrombin and promoting the formation of covalent complexes between antithrombin and target proteases, the heparin, LMWH, or fondaparinux dissociates from the complex and can then catalyze other antithrombin molecules.

Platelet factor 4, a cationic protein released from α-granules during platelet activation, binds heparin and prevents it from interacting with antithrombin. This phenomenon may limit the activity of heparin in the vicinity of platelet-rich thrombi. Because LMWH and fondaparinux have a lower affinity for platelet factor 4, these agents may retain their activity in the vicinity of such thrombi to a greater extent than heparin.

Miscellaneous Pharmacological Effects. High doses of heparin can interfere with platelet aggregation and prolong the bleeding time. In contrast, LMWH and fondaparinux have little effect on platelets. Heparin “clears” lipemic plasma in vivo by causing the release of lipoprotein lipase into the circulation. Lipoprotein lipase hydrolyzes triglycerides to glycerol and free fatty acids. The clearing of lipemic plasma may occur at concentrations of heparin below those necessary to produce an anticoagulant effect.

Clinical Use. Heparin, LMWH, or fondaparinux can be used to initiate treatment of deep vein thrombosis and pulmonary embolism. They also can be used for the initial management of patients with unstable angina or acute myocardial infarction (Gara et al., 2013; Roffi et al., 2015). For most of these indications, LMWH or fondaparinux has replaced continuous heparin infusions because of their pharmacokinetic advantages, which permit subcutaneous administration once or twice daily in fixed or weight-adjusted doses without coagulation monitoring. Thus, LMWH or fondaparinux can be used for out-of-hospital management of patients with deep vein thrombosis or pulmonary embolism. Heparin or LMWH is used during coronary balloon angioplasty with or without stent placement to prevent thrombosis. Fondaparinux is not used in this setting because of the risk of catheter thrombosis, a complication caused by catheter-induced activation of factor XII; longer heparin molecules are better than shorter ones for blocking this process. Cardiopulmonary bypass circuits also activate factor XII, which can cause clotting of the oxygenator. Heparin remains the agent of choice for surgery requiring cardiopulmonary bypass. Heparin or LMWH also is used to treat selected patients with disseminated intravascular coagulation. Subcutaneous administration of low-dose heparin or LMWH is often used for thromboprophylaxis in immunocompromised medically ill patients (Kahn et al., 2012) or in those who have undergone major surgery (Falck-Ytter et al., 2012; Gould et al., 2012).

Unlike the oral anticoagulants, heparin, LMWH, and fondaparinux do not cross the placenta and have not been associated with fetal malformations, making them the drugs of choice for anticoagulation during pregnancy. Heparin, LMWH, and fondaparinux do not appear to increase fetal mortality or prematurity. If possible, the drugs should be discontinued 24 h before delivery to minimize the risk of postpartum bleeding.

| TABLE 32–1 | COMPARISON OF THE FEATURES OF SUBCUTANEOUS HEPARIN, LOW-MOLECULAR-WEIGHT HEPARIN, AND FONDAPARINUX |
|---|---|---|---|
| FEATURES | HEPARIN | LMWH | FONDAPARINUX |
| Source | Biological | Biological | Synthetic |
| Mean molecular weight (Da) | 15,000 | 5000 | 1500 |
| Target | Xa and IIa | Xa and IIa | Xa |
| **Subcutaneous** | | | |
| Bioavailability (%) | 30 (at low doses) | 90 | 100 |
| $t_{1/2}$ (h) | 1–8* | 4 | 17 |
| Renal excretion | No | Yes | Yes |
| Antidote effect | Complete | Partial | None |
| Thrombocytopenia | <5% | <1% | <0.1% |

*Half life $t_{1/2}$ is dose dependent; half life is 1 h with 5000 units given subcutaneously and can extend to 8 h with higher doses.
**Figure 32-5**  Mechanism of action of heparin, LMWH, and fondaparinux, a synthetic pentasaccharide. A. Heparin binds to antithrombin via its pentasaccharide sequence. This induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, heparin must simultaneously bind to antithrombin and thrombin. Only heparin chains composed of at least 18 saccharide units (MW ~ 5400 Da) are of sufficient length to perform this bridging function. With a mean MW of approximately 15,000 Da, virtually all of the heparin chains are long enough to do this. B. LMWH has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin because at least half of the LMWH chains (mean MW ~ 4500–5000 Da) are too short to bridge antithrombin to thrombin. C. The pentasaccharide accelerates only factor Xa inhibition by antithrombin; the pentasaccharide is too short to bridge antithrombin to thrombin.

**ADME.** Heparin, LMWH, and fondaparinux are not absorbed through the GI mucosa and must be given parenterally. Heparin is given by continuous intravenous infusion, intermittent infusion every 4–6 h, or subcutaneous injection every 8–12 h. Heparin has an immediate onset of action when given intravenously. In contrast, there is considerable variation in the bioavailability of heparin given subcutaneously, and the onset of action is delayed by 1–2 h. LMWH and fondaparinux are absorbed more uniformly after subcutaneous injection. The $t_{1/2}$ of heparin in plasma depends on the dose administered. When doses of 100, 400, or 800 units/kg of heparin are injected intravenously, the half-lives are about 1, 2.5, and 5 h, respectively. Heparin appears to be cleared and degraded more uniformly after subcutaneous injection. A small amount of intact heparin appears in the urine.

Both LMWH and fondaparinux have longer biological half-lives than heparin, 4–6 and 17 h, respectively. Because these smaller heparin fragments are cleared almost exclusively by the kidneys, the drugs can accumulate in patients with renal impairment and lead to bleeding. Both LMWH and fondaparinux are contraindicated in patients with a creatinine clearance below 30 mL/min. In addition, thromboprophylaxis with fondaparinux is contraindicated in patients undergoing hip fracture, hip replacement, knee replacement, or abdominal surgery who have a body weight less than 50 kg.

**Administration and Monitoring.** Full-dose heparin usually is administered by continuous intravenous infusion. Treatment of venous thromboembolism is initiated with a fixed-dose bolus injection of 5000 units or with a weight-adjusted bolus, followed by 800–1600 units/h delivered by an infusion pump. Therapy is monitored by measuring the aPTT. The therapeutic range for heparin is considered to be that which is equivalent to a plasma heparin level of 0.3–0.7 units/mL, as determined with an
MODULATION OF PULMONARY, RENAL, AND CARDIOVASCULAR FUNCTION

Therapeutic anticoagulation with heparin.

Antithrombin deficiency may require antithrombin concentrate to achieve therapeutic aPTT or anti–factor Xa level is achieved. Patients with severe contrast, with true resistance, heparin doses need to be increased until a

Pseudoresistance to heparin occurs if the anti–factor Xa level is therapeutic. In very high doses of heparin, so a less-sensitive coagulation test, the ACT, is employed to monitor therapy in this situation.

For therapeutic purposes, heparin also can be administered subcutaneously on a twice-daily basis. A total daily dose of about 35,000 units administered as divided doses every 8–12 hours is sufficient to achieve an aPTT of twice the control value (measured midway between doses). For low-dose heparin therapy (to prevent venous thromboembolism in hospitalized medical or surgical patients), a subcutaneous dose of 5000 units is given two or three times daily.

Heparin Resistance. Patients who fail to achieve a therapeutic aPTT with daily doses of heparin of 35,000 units or more are considered to have heparin resistance, which may reflect pseudo- or true resistance. Concomitant measurement of the aPTT and the anti–factor Xa level distinguishes between these two possibilities. With heparin pseudoresistance, the anti–factor Xa level is therapeutic despite the subtherapeutic aPTT, whereas true heparin resistance both the anti–factor Xa level and the aPTT are subtherapeutic. Pseudoresistance to heparin occurs if the aPTT is shorter than the control value prior to initiating heparin treat-

ment because of high concentrations of factor VIII and fibrinogen. True heparin resistance occurs because of high plasma levels of proteins that compete with antithrombin for heparin binding or because of antithrombin deficiency. Heparin does not require dose adjustment in patients with pseudoresistance because the anti–factor Xa level is therapeutic. In contrast, with true resistance, heparin doses need to be increased until a therapeutic aPTT or anti–factor Xa level is achieved. Patients with severe antithrombin deficiency may require antithrombin concentrate to achieve therapeutic anticoagulation with heparin.

LMWH Preparations

Enoxaparin and dalteparin are the LMWH preparations marketed in the U.S.; tinzaparin is available in other countries. The composition of these agents differs, as do their dosing regimens. Because LMWH produces a relatively predictable anticoagulant response, monitoring is not done rou-

tinely. Patients with renal impairment may require monitoring with an anti–factor Xa assay because this condition can prolong the $t_{1/2}$ and slow the elimination of LMWH. Obese patients, pregnant women, and children given LMWH also may require monitoring.

Fondaparinux

Fondaparinux, a synthetic pentasaccharide, is administered by subcuta-

neous injection, reaches peak plasma levels in 2 h, has a $t_{1/2}$ of 17 h, and is excreted in the urine. Because of the risk of accumulation and subsequent bleeding, fondaparinux should not be used in patients with a creatinine clearance less than 30 mL/min. Fondaparinux can be given subcutane-

ously once a day at a fixed or weight-adjusted dose without coagulation monitoring. Fondaparinux is much less likely than heparin or LMWH to trigger heparin-induced thrombocytopenia, and the drug has been used successfully to treat patients with this condition. Fondaparinux is approved for thromboprophylaxis in patients undergoing hip or knee sur-

gery or surgery for hip fracture and for initial therapy of patients with deep vein thrombosis or pulmonary embolism. In some countries, but not the U.S., fondaparinux also is licensed as an alternative to heparin or LMWH in patients with acute coronary syndrome. For this indication and for thromboprophylaxis, fondaparinux is administered subcutaneously once daily at a dose of 2.5 mg.

Bleeding. The major untoward effect of heparin, LMWH, and fondaparinux is bleeding. Major bleeding occurs in 1%–5% of patients treated with intravenous heparin for venous thromboembolism. The incidence of bleeding is somewhat less in patients treated with LMWH for this indication. Often, an underlying cause for bleeding is present, such as recent surgery, trauma, peptic ulcer disease, or platelet dysfunction due to concomitant administration of aspirin or other antiplatelet drugs.

The anticoagulant effect of heparin disappears within hours of dis-

continuation of the drug. Mild bleeding due to heparin usually can be controlled without administration of an antagonist. If life-threatening hemorrhage occurs, heparin can rapidly be reversed by the intravenous infusion of protamine sulfate (a mixture of basic polypeptides isolated from salmon sperm), which binds tightly to heparin and neutralizes its anticoagulant effect. Protamine also interacts with platelets, fibrino-

gen, and other plasma proteins and may cause an anticoagulant effect of its own. Therefore, one should give the minimal amount of protamine required to neutralize the heparin present in the plasma. This amount is 1 mg of protamine for every 100 units of heparin remaining in the patient; protamine is given intravenously at a slow rate (up to a maximum of 50 mg over 10 min). Protamine binds only long heparin molecules. Therefore, protamine only partially reverses the anticoagulant activity of LMWH and has no effect on that of fondaparinux.

Heparin-Induced Thrombocytopenia. Heparin-induced thrombocytopenia (platelet count < 150,000/mL or a 50% decrease from the pretreatment value) occurs in about 0.5% of medical patients 5–10 days after initiation of therapy with heparin. Although the incidence is lower, thrombocytopenia also occurs with LMWH and rarely with fondaparinux. Life-threatening thrombotic complications that can lead to limb amputation, which occurs in up to one-half of the affected heparin-treated patients may and may precede the onset of thrombocytopenia. Women are twice as likely as men to develop this condition, and heparin-induced thrombocytopenia is more common in surgical patients than medical patients.

Venous thromboembolism occurs most commonly, but arterial throm-

bosis causing limb ischemia, myocardial infarction, or stroke also occurs. Bilateral renal hemorrhage, skin lesions at the site of subcutaneous hep-

arin injection, and a variety of systemic reactions may accompany hep-

arin-induced thrombocytopenia. The development of immunoglobulin G antibodies against complexes of heparin with platelet factor 4 (or, rarely, other chemokines) causes most of these reactions.

Heparin or LMWH should be discontinued immediately if unexplained thrombocytopenia or any of the clinical manifestations mentioned occur 5 or more days after beginning therapy, regardless of the dose or route of administration. The diagnosis of heparin-induced thrombocytopenia can be confirmed with a heparin-dependent platelet activation assay or an immunoassay for antibodies that react with heparin–platelet factor 4 complexes. Because thrombotic complications may occur after cessation of therapy, an alternative anticoagulant such as bivalirudin or argatroban (see the next section) or fondaparinux should be administered to patients with heparin-induced thrombocytopenia. LMWH should be avoided because it cross-reacts with heparin antibodies. Warfarin may precipitate venous limb gangrene or skin necrosis in patients with heparin-induced thrombocytopenia and should not be used until the platelet count returns to normal.

Other Toxicities. Abnormalities of hepatic function tests occur frequent-

ly in patients who are receiving heparin or LMWH. Osteoporosis occurs occasionally in patients who have received therapeutic doses of heparin (>20,000 units/d) for extended periods (e.g., 3–6 months). The risk of osteoporosis is lower with LMWH or fondaparinux than it is with heparin. Heparin can inhibit the synthesis of aldosterone by the adrenal glands and occasionally causes hyperkalemia.

Other Parenteral Anticoagulants

Desirudin and Lepirudin

Desirudin and lepirudin (not available in the U.S.) are recombinant forms of hirudin. Desirudin is indicated for thromboprophylaxis in patients undergoing elective hip replacement surgery. Both desirudin and lepirudin are also used for treating thrombosis in the setting of heparin-in-

duced thrombocytopenia (Kelton et al., 2013). Desirudin and lepirudin are eliminated by the kidneys; the $t_{1/2}$ is about 2 h after subcutaneous

SECTION III MODULATION OF PULMONARY, RENAL, AND CARDIOVASCULAR FUNCTION

Brunton_Ch32_p0585-p0604.indd 591
07/09/17 2:07 PM
administration and about 10 min after intravenous infusion. Both drugs should be used cautiously in patients with decreased renal function, and serum creatinine and aPTT should be monitored daily.

**Bivalirudin**

Bivalirudin is a synthetic 20–amino acid polypeptide that directly inhibits thrombin. Bivalirudin is administered intravenously and is used as an alternative to heparin in patients undergoing coronary angioplasty or cardiopulmonary bypass surgery (Barria Perez et al. 2016). Patients with heparin-induced thrombocytopenia or a history of this disorder also can be given bivalirudin instead of heparin during coronary angioplasty. The 1/2 of bivalirudin is 25 min; dosage reductions are recommended for patients with renal impairment.

**Argatroban**

Argatroban, a synthetic compound based on the structure of L-arginine, binds reversibly to the active site of thrombin. Argatroban is administered intravenously and has a 1/2 of 40–50 min. It is metabolized in the liver and excreted in the bile. Therefore, argatroban can be used in patients with renal impairment, but dose reduction is required for patients with hepatic insufficiency. Argatroban is licensed for the prophylaxis or treatment of patients with, or at risk of developing, heparin-induced thrombocytopenia (Grouzi, 2014). In addition to prolonging the aPTT, argatroban prolongs the PT, which can complicate the transitioning of patients from argatroban to warfarin. A factor X assay can be used instead of the PT to monitor warfarin in these patients.

**Mechanism of Action**

Coagulation factors II, VII, IX, and X and proteins C and S are synthesized in the liver and are biologically inactive unless 9–13 of the amino-terminal Glu residues are γ-carboxylated to form the Ca2+-binding Gla domain. This carboxylation reaction requires CO2, O2, and reduced vitamin K and is catalyzed by γ-glutamyl carboxylase (Figure 32–6). Carboxylation is coupled to the oxidation of vitamin K to its corresponding epoxide form. Reduced vitamin K must be regenerated from the epoxide form for sustained carboxylation and synthesis of functional proteins. The enzyme that catalyzes this reaction, VKOR, is inhibited by therapeutic doses of warfarin.

At therapeutic doses, warfarin decreases the functional amount of each vitamin K–dependent coagulation factor made by the liver by 30%–70%. Warfarin has no effect on the activity of fully γ-carboxylated factors already in the circulation, and these must be cleared before it can produce an anticoagulant effect. The approximate 1/2 values of factors VII, IX, X, and II are 6, 24, 36, and 50 h, respectively, while the 1/2 values of protein C and protein S are 8 and 24 h, respectively. Because of the long 1/2 of some of the coagulation factors, in particular factor II, the full antithrombotic effect of warfarin is not achieved for 4 to 5 days. For this reason, warfarin must be overlapped with a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux, in patients with thrombosis or at high risk for thrombosis.

**ADME**

The bioavailability of warfarin is nearly complete when the drug is administered orally, intravenously, or rectally. Generic warfarin tablets may vary in their rate of dissolution, and this may cause some variation in the rate and extent of absorption. Food in the GI tract also can decrease the rate of absorption. Plasma warfarin concentrations peak in 2–8 h. Warfarin is administered as a racemic mixture of S- and R-warfarin. S-Warfarin is 3- to 5-fold more potent than R-warfarin and is mainly metabolized by CYP2C9. Inactive metabolites of warfarin are excreted...
in urine and stool. The $t_{1/2}$ varies (25–60 h), but the duration of action of warfarin is 2–5 days.

Table 32–2 summarizes the effects of known genetic factors on warfarin dose requirements. Polymorphisms in two genes, CYP2C9 and VKORC1, account for most of the genetic contribution to variability in warfarin response (International Warfarin Pharmacogenetics Consortium, 2009; McClain et al., 2008). CYP2C9 variants affect warfarin pharmacokinetics, whereas VKORC1 variants affect warfarin pharmacodynamics. Common variations in the CYP2C9 gene (designated CYP2C9*2 and *3), encode an enzyme with decreased activity and are associated with higher drug concentrations and reduced warfarin dose requirements. VKORC1 variants are more prevalent than those of CYP2C9, particularly in Asians, followed by European Americans and African Americans (Limdi et al., 2015). The warfarin dose requirement is decreased in patients with these variants (Shi et al., 2015). Point-of-care methods for CYP2C9 and VKORC1 genotyping and algorithms that incorporate genotype information have been developed to facilitate precision dosing of warfarin. It remains uncertain, however, whether precision dosing improves clinical outcome compared with usual warfarin management.

**Clinical Use**

Vitamin K antagonists are used to prevent the progression or recurrence of acute deep vein thrombosis or pulmonary embolism following an initial course of heparin, LMWH, or fondaparinux (Kearon et al., 2016). They also are effective in preventing stroke or systemic embolization in patients with atrial fibrillation, mechanical heart valves, or ventricular assist devices.

Prior to initiation of therapy, laboratory tests are used in conjunction with the history and physical examination to uncover hemostatic defects that might make the use of warfarin more dangerous (e.g., congenital coagulation factor deficiency, thrombocytopenia, hepatic or renal insufficiency, vascular abnormalities). Thereafter, the INR calculated from the patient’s PT is used to monitor the extent of anticoagulation and compliance. Therapeutic INR ranges for various clinical indications have been established and reflect the extent of anticoagulation that reduces the morbidity from thromboembolic disease while minimally increasing the risk of serious hemorrhage. For most indications, an INR range of 2–3 is used. A higher INR range (2.5–3.5) is recommended for patients with mechanical heart valves in the mitral position or for patients with mechanical valves in another position who have concomitant atrial fibrillation or a prior history of stroke.

For treatment of acute venous thromboembolism, heparin, LMWH, or fondaparinux is usually continued for at least 5 days after warfarin therapy is begun. The parenteral agent is stopped when the INR is in the therapeutic range on 2 consecutive days. This overlap allows for adequate depletion of vitamin K–dependent coagulation factors with long half-lives, especially factor II. Frequent INR measurements are indicated at the onset of therapy to ensure that a therapeutic effect is obtained. Once a stable dose of warfarin has been identified, the INR can be monitored every 3 to 4 weeks.

**Dosage**

The usual adult dosage of warfarin is 2–5 mg/d for 2–4 days, followed by 1–10 mg/d as indicated by measurements of the INR (see the functional definition of INR in the section on clinical use). A lower initial dose should be given to patients with an increased risk of bleeding, including the elderly.

**Interactions**

Warfarin interactions can be caused by drugs, foods, or genetic factors that alter (1) uptake or metabolism of warfarin or vitamin K; (2) synthesis, function, or clearance of clotting factors; or (3), the integrity of any epithelial surface. Reduced warfarin efficacy can occur because of reduced absorption (e.g., binding to cholestyramine in the GI tract) or increased hepatic clearance from induction of hepatic enzymes (e.g., CYP2C9 induction by barbiturates, carbamazepine, or rifampin). Warfarin has a decreased volume of distribution and a short $t_{1/2}$ with hypoprothrombinemia, such as occurs with nephrotic syndrome. Relative warfarin resistance can also be caused by ingestion of large amounts of vitamin K–rich foods or supplements or by increased levels of coagulation factors during pregnancy.

Drug interactions that enhance the risk of hemorrhage in patients taking warfarin include decreased metabolism due to CYP2C9 inhibition by amidodarone, azole antifungals, cimetidine, clopidogrel, cotrimoxazole, disulfiram, fluoxetine, isoniazid, metronidazole, sulfipyrazone, tolcapone, or zafirlukast. Relative deficiency of vitamin K may result from inadequate diet (e.g., postoperative patients on parenteral fluids), especially when coupled with the elimination of intestinal flora by antimicrobial agents. Gut bacteria synthesize vitamin K and are an important source of this vitamin. Consequently, antibiotics can cause an increase in the INR in patients on warfarin. Low concentrations of coagulation factors may result from impaired hepatic function, congestive heart failure, or hypermetabolic states, such as hyperthyroidism; generally, these conditions enhance the effect of warfarin on the INR. Serious interactions that do not alter the

Polymorphisms in two genes, CYP2C9 and VKORC1, largely account for the genetic contribution to the variability in warfarin response. CYP2C9 variants affect warfarin pharmacokinetics. CYP2C9 metabolizes warfarin, and the non-1/1 variants are less active than CYP2C9*1/1, necessitating a reduction in dose. VKORC1 variants affect warfarin pharmacodynamics. VKORC1 is the target of coumarin anticoagulants such as warfarin. The non-A/A and A/A forms have decreased requirements for warfarin.

Source: Ghimire LV, Stein CM. Warfarin pharmacogenetics. Goodman and Gilman Online.
INR include inhibition of platelet function by agents such as aspirin and gastritis or frank ulceration induced by anti-inflammatory drugs. Agents may have more than one effect (e.g., clofibrate increases the rate of turnover of coagulation factors and inhibits platelet function).

**Hypersensitivity to Warfarin**

About 10% of patients require less than 1.5 mg/d of warfarin to achieve an INR of 2–3. These patients often possess variants of CYP2C9 or VKORC1; these affect the pharmacokinetics or pharmacodynamics of warfarin, respectively. Supplementation with low daily doses of vitamin K renders these patients less sensitive to warfarin and may result in more stable dosing.

**Adverse Effects**

**Bleeding.** The most common side effect of warfarin is bleeding. The risk of bleeding increases with the intensity and duration of anticoagulant therapy, the use of other medications that interfere with hemostasis, and the presence of an anatomical source of bleeding. The incidence of major bleeding episodes is generally less than 3% per year in patients treated to a target INR of 2–3. The risk of intracranial hemorrhage increases dramatically with an INR greater than 4, although up to two-thirds of intracranial bleeds on warfarin occur when the INR is therapeutic.

If the INR is above the therapeutic range and the patient is not bleeding or in need of a surgical procedure, warfarin can be held temporarily and restarted at a lower dose once the INR is within the therapeutic range. If the INR is 10 or greater, vitamin K, can be given orally at a dose of 2.5 to 5 mg. These doses of oral vitamin K generally cause the INR to decrease substantially within 24–48 h without rendering the patient resistant to further warfarin therapy. Higher doses or parenteral administration may be required if more rapid correction of the INR is necessary. The effect of vitamin K, is delayed for at least several hours because reversal of anticoagulation requires synthesis of fully carboxylated coagulation factors. If immediate hemostatic competence is necessary because of serious bleeding or profound warfarin overdose, adequate concentrations of vitamin K–dependent coagulation factors can be restored by transfusion of four-factor prothrombin complex concentrate, supplemented with 10 mg of vitamin K, given by slow intravenous infusion. Vitamin K, administered intravenously carries the risk of anaphylactoid reactions. Patients who receive high doses of vitamin K, may become unresponsive to warfarin for several days, but heparin or LMWH can be given if continued anticoagulation is required.

**Birth Defects.** Administration of warfarin during pregnancy causes birth defects and abortion. CNS abnormalities have been reported following exposure during the second and third trimesters. Fetal or neonatal hemorrhage and intrauterine death may occur, even when maternal INR values are within the therapeutic range. Vitamin K antagonists should not be used during pregnancy, but heparin or LMWH can be used safely.

**Skin Necrosis.** Warfarin-induced skin necrosis is a rare complication characterized by the appearance of skin lesions 3–10 days after treatment is initiated. The lesions typically are on the extremities, but adipose tissue, the penis, and the female breast also may be involved. Skin necrosis occurs in patients with protein C or S deficiency or in those with heparin-induced thrombocytopenia.

**Other Toxicities.** A reversible, sometimes painful, blue-tinged discoloration of the plantar surfaces and sides of the toes that blanches with pressure and fades with elevation of the legs (purple toe syndrome) may develop 3–8 weeks after initiation of therapy with warfarin; cholesterol emboli released from atheromatous plaques have been implicated as the cause. Other infrequent reactions include alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramps, and anorexia.

**Direct Oral Anticoagulants**

**Direct Oral Thrombin Inhibitor**

**Dabigatran**

Dabigatran etexilate is a synthetic prodrug with a molecular weight of 628 Da.

**Mechanism of Action.** Dabigatran etexilate is rapidly converted to dabigatran by plasma esterases. Dabigatran competitively and reversibly blocks the active site of free and clot-bound thrombin. In turn, this blocks thrombin-mediated conversion of fibrinogen to fibrin, feedback activation of coagulation, and platelet activation.

**ADME.** Dabigatran has oral bioavailability of about 6%, a peak onset of action in 2 h, and a plasma \( t_{1/2} \) of 12–14 h. Dabigatran is given twice a day in capsule form. The bioavailability of the drug is altered if capsules are chewed or broken prior to ingestion. Therefore, the capsules should be swallowed whole. Circulating dabigatran is 35% bound to plasma proteins. Around 80% of absorbed dabigatran is excreted unchanged by the kidneys. A dosage reduction is required when dabigatran is administered to patients with severe renal impairment (creatinine clearance 15 to 30 mL/min). Dosage recommendations are not available for patients with a creatinine clearance below 15 mL/min.

When given in fixed doses, dabigatran etexilate produces such a predictable anticoagulant response that routine coagulation monitoring is unnecessary. Although dabigatran prolongs the aPTT, the values plateau with higher drug levels. Dabigatran has an unreliable effect on the INR. The thrombin time is too sensitive to use to monitor dabigatran therapy because the test is markedly prolonged with even low levels of drug. To circumvent this problem, a diluted thrombin time assay has been developed. By comparing the results with those obtained with dabigatran calibrators, this test can be used to quantify plasma dabigatran concentrations.

**Therapeutic Uses.** Dabigatran is licensed for treatment of acute venous thromboembolism after at least 5 days of parenteral anticoagulation with heparin, LMWH, or fondaparinux (Schulman et al., 2009) and for secondary prevention of venous thromboembolism (Beyer-Westendorf and Ageno, 2015; Gomez-Outes et al., 2015). Dabigatran also is licensed for stroke prevention in patients with nonvalvular atrial fibrillation (Connolly et al., 2009). It is contraindicated in patients with mechanical heart valves (Eikelboom et al., 2013). In some countries, lower-dose regimens of once-daily dabigatran are licensed for thromboprophylaxis after knee or hip arthroplasty. Dabigatran is contraindicated for stroke prevention in patients with mechanical heart valves.

**Adverse Effects.** Bleeding is the major side effect of dabigatran. In elderly patients with atrial fibrillation, the annual risk of major bleeding with dabigatran 150 mg twice daily is similar to that with warfarin, about 5.0%. However, the risk of intracranial bleeding is reduced by 70% with dabigatran compared with warfarin. In contrast, the risk of GI bleeding is higher with dabigatran, particularly in those over 75 years of age. Additional risks for bleeding with dabigatran include renal impairment and concurrent use of antiplatelet agents or nonsteroidal anti-inflammatory drugs.

**Drug Interactions.** Dabigatran is a substrate for P-glycoprotein, so drugs that inhibit or induce P-glycoprotein have the potential to increase or decrease plasma dabigatran concentrations, respectively. Verapamil, dronedarone, quinidine, ketoconazole, and clarithromycin can increase dabigatran concentrations, while rifampicin may decrease the concentration.

**Direct Oral Factor Xa Inhibitors**

**Rivaroxaban, Apixaban, and Edoxaban**

**Mechanism of Action.** Rivaroxaban, apixaban, and edoxaban inhibit free and clot-associated factor Xa, which results in reduced thrombin generation. In turn, platelet aggregation and fibrin formation are suppressed.

**ADME.** Rivaroxaban has 80% oral bioavailability, a peak onset of action in 3 h, and a plasma \( t_{1/2} \) of 7–11 h. Maximum absorption of rivaroxaban occurs in the stomach, and when given in therapeutic doses, the drug should be administered with a meal to enhance absorption. Rivaroxaban is provided in tablet form; the tablet can be crushed and delivered via nasogastric tube. Rivaroxaban is 95% plasma protein bound. About one-third of the drug is excreted unchanged in the urine; the remainder is
metabolized by the hepatic CYP3A4 system, and inactive metabolites are excreted equally in the urine and feces. Rivaroxaban exposure is increased in patients with renal impairment or severe hepatic dysfunction. The therapeutic dose of rivaroxaban is reduced from 20 mg once daily to 15 mg once daily if the creatinine clearance is 15–50 mL/min. The drug should not be used in those with a lower creatinine clearance.

The bioavailability of apixaban is around 30%, and peak concentrations are achieved 1 to 3 h after ingestion. Food does not affect absorption, and the drug can be administered as a whole tablet or the tablet can be crushed in water and delivered via a nasogastric tube. Apixaban is 87% plasma protein bound, and about 27% of the drug is cleared unchanged via the kidneys. Apixaban is metabolized by the hepatic CYP3A4 system, and metabolites are excreted in the bile, intestines, and urine. The usual dose of apixaban is 5 mg twice daily. The dose is reduced to 2.5 mg twice daily in patients who have two of the following three characteristics: age over 80 years, body weight of 60 kg or less, or serum creatinine concentration of 1.5 mg/dL or higher. In patients with acute venous thromboembolism, patients start apixaban at a dose of 10 mg twice daily for 7 days, and the dose is then decreased to 5 mg twice daily thereafter. For those requiring treatment beyond 6 to 12 months, the apixaban dose can be decreased to 2.5 mg twice daily.

The bioavailability of edoxaban is 62%, and peak drug concentrations are achieved 1 to 2 h after ingestion. Food does not affect absorption. Edoxaban is 55% protein bound. Of the absorbed edoxaban, about 50% is eliminated as unchanged drug in the urine. There is minimal hepatic metabolism, and liver disease does not affect drug pharmacodynamics. Drug exposure is increased by renal impairment, low body weight, and concomitant intake of potent P-glycoprotein inhibitors. Therefore, the dose of edoxaban should be reduced from 60 to 30 mg once daily in patients with a creatinine clearance between 15 and 50 mL/min, in those with a body weight of 60 kg or less, or in those taking quinidine, dronedarone, rifampin, erythromycin, ketoconazole, or cyclosporine. Edoxaban is contraindicated in those with a creatinine clearance below 15 mL/min. Edoxaban is also not recommended in patients with a high creatinine clearance over 95 mL/min because of increased risk of ischemic stroke compared with warfarin.

Rivaroxaban, apixaban, and edoxaban are given in fixed doses and do not require routine coagulation monitoring. The drugs affect the PT more than the aPTT, but they prolong the PT to a variable extent, and this test does not provide a reliable measure of their anticoagulant activity. Anti-factor Xa assays using specific drug calibrators can be used to measure drug levels. Renal function should be assessed at least yearly in patients taking oral factor Xa inhibitors or more frequently in patients with renal dysfunction.

**Therapeutic Uses.** Rivaroxaban, apixaban, and edoxaban are licensed for stroke prevention in patients with atrial fibrillation (Giugliano et al., 2013; Granger et al., 2011; Patel et al., 2011) and for treatment of acute deep vein thrombosis or pulmonary embolism (Beyer-Westendorf and Ageno, 2015; Gomez-Outes et al., 2015). For the last indication, edoxaban is only started after a minimum 3-day course of treatment with heparin, LMWH, or fondaparinux (Hokusai VTE Investigators, 2013). In contrast, rivaroxaban and apixaban can be started immediately without the need for heparin bridging (EINSTEIN investigators, 2010, 2011. Granzeria et al., 2016). Rivaroxaban and apixaban are also licensed for postoperative thromboprophylaxis in patients undergoing hip or knee arthroplasty (Falk-Ytter et al., 2012); for this indication, the drugs are given at doses of 10 mg once daily and 2.5 mg twice daily, respectively. All three drugs are contraindicated for stroke prevention in patients with mechanical heart valves.

**Adverse Effects.** As with all anticoagulants, the major adverse effect is bleeding. Rates of intracranial bleeding with rivaroxaban, apixaban, and edoxaban are at least 50% lower than with warfarin. Rates of bleeding in other sites are similar or lower than those with warfarin. The sole exception is the GI tract; rates of GI bleeding with rivaroxaban and edoxaban, but not apixaban, are higher than that with warfarin. The explanation for this difference is uncertain, but it may reflect the capacity of unabsorbed anticoagulant in the gut to promote bleeding from preexisting lesions. Despite the increased risk of GI bleeding, rates of life-threatening and fatal bleeding are lower with all of the oral factor Xa inhibitors than with warfarin. Like with other anticoagulants, the risk of bleeding with rivaroxaban, apixaban, or edoxaban is increased in patients taking concomitant antiplatelet agents or nonsteroidal anti-inflammatory agents.

**Drug Interactions.** All of the oral factor Xa inhibitors are substrates for P-glycoprotein. Consequently, potent inhibitors or inducers of P-glycoprotein will increase or decrease drug concentrations, respectively. Rivaroxaban and apixaban are metabolized by CYP3A4, whereas edoxaban undergoes only minimal CYP3A4-mediated metabolism. Plasma levels of rivaroxaban and apixaban are reduced by potent inducers of both P-glycoprotein and CYP3A4, such as carbamazepine, phenytoin, rifampin, and St. John's wort and increased by potent inhibitors, such as dronedarone, ketoconazole, itraconazole, ritonavir, clarithromycin, erythromycin, and cyclosporine.

**Reversal Agents for Direct Oral Anticoagulants**

Life-threatening bleeding can occur with the direct oral anticoagulants, and patients taking these drugs may require urgent surgery or interventions. Therefore, the availability of specific reversal agents streamlines the management of such patients. Idarucizumab, the reversal agent for dabigatran, is licensed. Andexanet alfa, a reversal agent for rivaroxaban, apixaban, and edoxaban, is in advanced phase 3 evaluation, while ciraparantag, a potential reversal agent for all of the direct anticoagulants, is at an earlier stage of development.

If specific reversal agents are not available, prothrombin complex concentrate, activated prothrombin complex concentrate, or recombinant factor VIIa have been recommended to manage patients taking dabigatran, rivaroxaban, apixaban, or edoxaban who present with life-threatening bleeding, such as intracranial or pericardial bleeding. In patients taking dabigatran who present with serious bleeding in the setting of acute renal failure, hemodialysis can be used to remove dabigatran from the circulation. Dialysis is of no value for removal of rivaroxaban, apixaban or edoxaban because of their higher protein binding.

**Idarucizumab**

A specific reversal agent for dabigatran, idarucizumab is a humanized mouse monoclonal antibody fragment directed against dabigatran. The antibody binds dabigatran with an affinity 350-fold higher than that of dabigatran for thrombin, and the essentially irreversible idarucizumab–dabigatran complex is cleared by the kidneys. Idarucizumab is infused as two intravenous boluses, each of 2.5 g. It rapidly reverses the anticoagulant effects of dabigatran, and patients have then safely undergone major surgery (Pollack et al., 2015).

**Andexanet Alfa**

Designed as a decoy for the oral factor Xa inhibitors, andexanet alfa is a recombinant analogue of factor Xa that has the active site serine residue replaced with an alanine residue to eliminate catalytic activity and the Glu domain removed to preclude its incorporation in the prothrombinase complex. Andexanet is administered as an intravenous bolus followed by a 2-h infusion. By sequestering circulating factor Xa inhibitors, andexanet rapidly reverses the anti–factor Xa activity produced by these agents and restores thrombin generation (Siegal et al., 2015). Higher doses of andexanet are needed to reverse rivaroxaban or edoxaban than apixaban. An ongoing phase 3 study is evaluating the effect of andexanet in patients taking these agents who present with serious bleeding.

**Ciraparantag**

Ciraparantag is a synthetic, small cationic molecule that is reported to bind dabigatran, rivaroxaban, apixaban, and edoxaban, as well as heparin and LMWH. In healthy volunteers given edoxaban, an intravenous bolus of ciraparantag restored the whole-blood clotting time to normal. Ciraparantag has yet to be evaluated in patients.
Fibrinolytic Drugs

Fibrinolytic drugs initiate the fibrinolytic pathway, which is summarized in Figure 32–3. These agents include recombinant t-PA and its variants, urokinase and streptokinase, although the latter are rarely used.

Tissue Plasminogen Activator

Tissue plasminogen activator is a serine protease and a poor plasminogen activator in the absence of fibrin. When bound to fibrin, t-PA activates fibrin-bound plasminogen several 100-fold more rapidly than it activates plasminogen in the circulation. Because it has little activity except in the presence of fibrin, physiological t-PA concentrations of 5–10 ng/mL do not induce systemic plasmin generation. With therapeutic infusion of recombinant t-PA, the concentrations rise to 300–3000 ng/mL, which can induce systemic fibrinogen degradation. Clearance of t-PA primarily occurs via hepatic metabolism, and its t½ is about 5 min. t-PA is effective for treatment of acute myocardial infarction (Gara et al., 2013), acute ischemic stroke, and life-threatening pulmonary embolism (Meyer et al., 2014).

For coronary thrombolysis, t-PA is given as a 15-mg intravenous bolus, followed by 0.75 mg/kg over 30 min (not to exceed 50 mg) and 0.5 mg/kg (up to 35 mg accumulated dose) over the following hour. Recombinant variants of t-PA include reteplase and tenecteplase. They differ from native t-PA by having longer plasma half-lives that allow conventional bolus dosing. In addition, in contrast to t-PA, tenecteplase is relatively resistant to inhibition by PAI-1. Despite these apparent advantages, these agents are similar to t-PA in efficacy and toxicity.

Hemorrhagic Toxicity of Thrombolytic Therapy

The major toxicity of all thrombolytic agents is hemorrhage. It is due to (1) degradation of fibrin in hemostatic plugs at sites of vascular injury or (2) the systemic lytic state that results from the systemic generation of plasmin, which degrades fibrinogen and other coagulation factors, especially factors V and VIII. Contraindications to fibrinolytic therapy are listed in Table 32–3.

If heparin is used concurrently with t-PA, serious hemorrhage will occur in 2%–4% of patients. Intracranial hemorrhage is the most serious problem and can occur in up to 1% of patients. For this reason, mechanical reperfusion is preferred over systemic thrombolysis in patients with acute myocardial infarction with ST-segment elevation. In patients with acute ischemic stroke, the current standard of care is mechanical thrombus extraction, which can be done with or without adjunctive t-PA or tenecteplase.

| Absolute Contraindications | • Prior intracranial hemorrhage  
• Known structural cerebral vascular lesion  
• Known malignant intracranial neoplasm  
• Ischemic stroke within 3 months  
• Suspected aortic dissection  
• Active bleeding or bleeding diathesis (excluding menses)  
• Significant closed-head trauma or facial trauma within 3 months |

| Relative Contraindications | • Uncontrolled hypertension (systolic blood pressure > 180 mm Hg or diastolic blood pressure > 110 mm Hg)  
• Traumatic or prolonged CPR or major surgery within 3 weeks  
• Recent (within 2–4 weeks) internal bleeding  
• Noncompressible vascular punctures  
• For streptokinase: prior exposure (more than 5 days ago) or prior allergic reaction to streptokinase  
• Pregnancy  
• Active peptic ulcer  
• Current use of warfarin and INR > 1.7 |

Inhibitors of Fibrinolysis

e-aminocaproic acid and tranexamic acid

e-aminocaproic acid and tranexamic acid are lysine analogues that compete for lysine binding sites on plasminogen and plasmin, thereby blocking their interaction with fibrin. Therefore, these agents inhibit fibrinolysis and can reverse states that are associated with excessive fibrinolysis.

The main problem with their use is that thrombi that form during treatment are not degraded. For example, in patients with hematuria, ureteral obstruction by clots may lead to renal failure after treatment with e-aminocaproic acid or tranexamic acid. e-Aminocaproic acid has been used intravenously to reduce bleeding after prostatic surgery and orally to reduce bleeding after tooth extractions in hemophiliacs. e-Aminocaproic acid is absorbed rapidly after oral administration, and 50% is excreted unchanged in the urine within 12 h. For intravenous use, a loading dose of 4–5 g is given over 1 h, followed by an infusion of 1–1.25 g/h until bleeding is controlled. No more than 30 g should be given in a 24-h period. Rarely, the drug causes myopathy and muscle necrosis.

Tranexamic acid is given intravenously in trauma resuscitation and in patients with massive hemorrhage (CRASH2 trial investigators, 2010). It is also used to reduce operative bleeding in patients undergoing hip or knee arthroplasty or cardiac surgery. There appears to be little or no increased risk of thrombosis. Tranexamic acid is excreted in the urine; therefore, dose reduction is necessary in patients with renal impairment. Oral tranexamic acid is approved for treatment of heavy menstrual bleeding, usually given at a dose of 1 g four times daily for 4 days.

Antiplatelet Drugs

Platelet aggregates form the initial hemostatic plug at sites of vascular injury. Platelets also contribute to the pathological thrombi that lead to myocardial infarction, stroke, and peripheral arterial thrombosis. Potent inhibitors of platelet function have been developed in recent years. These drugs act by discrete mechanisms (Figure 32–7); thus, in combination, their effects are additive or even synergistic.

Aspirin

In platelets, the major COX-1 product is TxA2, a labile inducer of platelet aggregation and a potent vasoconstrictor. Aspirin blocks production of TxA2 by acetylation a serine residue near the active site of platelet COX-1. Because platelets do not synthesize new proteins, the action of aspirin on platelet COX-1 is permanent, lasting for the lifetime of the platelet (7–10 days). Thus, repeated doses of aspirin produce a cumulative effect on platelet function.

Complete inactivation of platelet COX-1 is achieved with a daily aspirin dose of 75 mg. Therefore, aspirin is maximally effective as an antithrombotic agent at doses much lower than those required for other actions of the drug. Numerous trials indicated that aspirin, when used as an antithrombotic drug, is maximally effective at doses of 30–325 mg/d. Higher doses do not improve efficacy and potentially are less efficacious because of inhibition of prostacyclin production, which can be largely spared by using lower doses of aspirin. Higher doses also increase toxicity, especially bleeding. Therefore, daily aspirin doses of 100 mg or less are used for most indications (Cohen et al., 2015; Ittaman et al., 2014). Nonsteroidal anti-inflammatory drugs that are reversible inhibitors of COX-1 have not been shown to have antithrombotic efficacy and in fact may even interfere with low-dose aspirin regimens (see Chapters 37 and 38).

Dipyridamole

Dipyridamole interferes with platelet function by increasing the intracellular concentration of cyclic AMP. This effect is mediated by inhibition of phosphodiesterase or by blockade of uptake of adenosine, thereby increasing the dwell time of adenosine at cell surface adenosine A1 receptors that link to the stimulation of platelet adenylyl cyclase. Dipyridamole is a vasodilator that, in combination with warfarin, inhibits embolization

**MODULATION OF PULMONARY, RENAL, AND CARDIOVASCULAR FUNCTION**

G protein–coupled receptors for ADP. The ADP-activated platelet P2Y1 receptor couples to the G_{q}-PLC-IP3–Ca^{2+} pathway and induces a shape change and aggregation. The P2Y_{12} receptor couples to Gi and, when activated by ADP, inhibits adenyl cyclase, resulting in lower levels of intracellular cyclic AMP and thereby less cyclic AMP–dependent inhibition of platelet activation. Both receptors must be stimulated to result in maximal platelet activation.

Clopidogrel is an irreversible inhibitor of P2Y_{12}. It has largely replaced ticlopidine because clopidogrel is more potent and less toxic, with thrombocytopenia and leukopenia occurring only rarely. Clopidogrel is a prodrug that requires metabolic activation in the liver. Therefore, it has a slow onset of action. It also has a slow offset of action because of its irreversible effect on P2Y_{12}. Metabolic activation of clopidogrel can be affected by polymorphisms in CYP2C19 that result in reduced or absent CYP2C19 activity. These polymorphisms contribute to the variable effect of clopidogrel on ADP-induced platelet aggregation. Inhibition of platelet activation is seen 2 h postingestion of a loading dose of clopidogrel, and platelets are affected for the remainder of their life span.

**P2Y_{12} Receptor Antagonists**

**Clopidogrel**

Clopidogrel is a thienopyridine prodrug that inhibits the P2Y_{12} receptor. Platelets contain two purinergic receptors, P2Y1 and P2Y12; both are G protein–coupled receptors for ADP. The ADP-activated platelet P2Y_{12} receptor couples to the G_{q}-PLC-IP3–Ca^{2+} pathway and induces a shape change and aggregation. The P2Y_{12} receptor couples to Gi and, when activated by ADP, inhibits adenyl cyclase, resulting in lower levels of intracellular cyclic AMP and thereby less cyclic AMP–dependent inhibition of platelet activation. Both receptors must be stimulated to result in maximal platelet activation.

Clopidogrel is an irreversible inhibitor of P2Y_{12}. It has largely replaced ticlopidine because clopidogrel is more potent and less toxic, with thrombocytopenia and leukopenia occurring only rarely. Clopidogrel is a prodrug that requires metabolic activation in the liver. Therefore, it has a slow onset of action. It also has a slow offset of action because of its irreversible effect on P2Y_{12}. Metabolic activation of clopidogrel can be affected by polymorphisms in CYP2C19 that result in reduced or absent CYP2C19 activity. These polymorphisms contribute to the variable effect of clopidogrel on ADP-induced platelet aggregation. Inhibition of platelet activation is seen 2 h postingestion of a loading dose of clopidogrel, and platelets are affected for the remainder of their life span.

**Therapeutic Uses.** Clopidogrel is somewhat better than aspirin for secondary prevention of stroke, and the combination of clopidogrel plus aspirin is superior to aspirin alone for prevention of recurrent ischemia in patients with unstable angina. The FDA-approved indications for clopidogrel are to reduce the rate of stroke, myocardial infarction, and death in patients with recent myocardial infarction or stroke, established peripheral artery disease, or acute coronary syndrome (Amsterdam et al., 2014; Gara et al., 2013; Park et al., 2016; Roffi et al., 2015; Zhang et al., 2015). Clopidogrel is often used in combination with aspirin after coronary stent implantation.

**Adverse Effects.** Clopidogrel increases the risk of bleeding, particularly when combined with aspirin or an anticoagulant. Thrombotic thrombocytopenic purpura can occur but is rare.

**Drug Interactions.** CY2919 inhibition by proton pump inhibitors (e.g., omeprazole, lansoprazole, deslansoprazole, and pantoprazole) may reduce conversion to the active metabolite of clopidogrel, which may contribute to the lower efficacy of clopidogrel when coadministered with proton pump inhibitors.

**Prasugrel**

The newest member of the thienopyridine class, prasugrel is a prodrug that requires metabolic activation in the liver. However, because the activation of prasugrel is more efficient than that of clopidogrel, prasugrel has a more rapid onset of action, and it produces greater and more predictable inhibition of ADP-induced platelet aggregation.

Prasugrel is rapidly and completely absorbed from the gut. It is hydrolyzed in the intestine to a thiolactone, which is then converted to the active metabolite in the liver. Virtually all of the absorbed prasugrel undergoes activation; by comparison, only 15% of absorbed clopidogrel undergoes metabolic activation. Because the active metabolites of prasugrel bind irreversibly to the P2Y_{12} receptor, its effect lasts the lifetime of the platelets. This slow offset of action can be problematic if patients require urgent surgery. Prasugrel is inactivated by methylation or conjugation with cysteine. Moderate renal or hepatic impairment does not appear to change the drug pharmacodynamics.

**Therapeutic Uses.** Prasugrel is indicated to reduce the rate of thrombotic cardiovascular events (including stent thrombosis) in patients with acute coronary syndrome who are managed with percutaneous coronary intervention (Gara et al., 2013; Guimarães and Tricoci, 2015; Lhermusier and Waksman, 2015). The incidence of cardiovascular death, myocardial infarction, and stroke is significantly lower with prasugrel than with clopidogrel, mainly reflecting a reduction in the incidence of nonfatal myocardial infarction. The incidence of stent thrombosis is also lower with prasugrel than with clopidogrel.

**Adverse Effects.** Prasugrel is associated with higher rates of fatal and life-threatening bleeding than clopidogrel. Because patients with a history of a prior stroke or transient ischemic attack are at particularly high risk of intracranial bleeding, the drug is contraindicated in such patients. Patients over 75 years of age should not be prescribed prasugrel because of the increased bleeding risk. After a loading dose of 60 mg, prasugrel is given once daily at a dose of 10 mg. The daily dose should be reduced to 5 mg in patients weighing less than 60 kg. No dose adjustment is required in patients with hepatic or renal impairment. If patients present with serious bleeding, platelet transfusion may be beneficial. Prasugrel has been reported to cause thrombotic thrombocytopenic purpura.

**Drug Interactions.** Concomitant administration of prasugrel with an anticoagulant or nonsteroidal anti-inflammatory drugs increases the risk of bleeding.

**Ticagrelor**

Ticagrelor is an orally active, reversible inhibitor of P2Y_{12}. The drug is given twice daily and not only has a more rapid onset and offset of action than clopidogrel, but also produces greater and more predictable inhibition of ADP-induced platelet aggregation. The bioavailability of ticagrelor is about 36%. It can be given as a whole tablet or crushed in water and administered via a nasogastric tube. Ticagrelor is metabolized by hepatic CYP3A4.
**Therapeutic Uses.** Ticagrelor is FDA-approved for reduction in the risk of cardiovascular death, myocardial infarction, and stroke in patients with acute coronary syndrome (Gara et al., 2013) or a history of myocardial infarction (Dobesh and Oestreich, 2014). In contrast to prasugrel in patients with acute coronary syndrome, which is only indicated in those undergoing percutaneous intervention, ticagrelor is indicated in those undergoing intervention and in those managed medically.

**Adverse Effects.** Dyspnea is reported in 17% of patients. This is often transient and not associated with pulmonary disease. Ticagrelor is associated with a higher risk of intracranial bleeding than clopidogrel and is contraindicated in patients with a history of prior intracranial bleeding. Platelet transfusion is ineffective in patients taking ticagrelor who present with serious bleeding, and a neutralizing antibody is under investigation for urgent reversal.

**Drug Interactions.** Concomitant aspirin at a dose greater than 100 mg daily may reduce the effectiveness of ticagrelor. Potent inhibitors of CYP3A4 (such as ketoconazole, itraconazole, voriconazole, clarithromycin, nefazodone, ritonavir, saquinavir, nelfinavir, indinavir, atazanavir, and telithromycin) and strong inducers of CYP3A4 (such as rifampin, phenytoin, carbamazepine, and phenobarbital) should be avoided. Ticagrelor increases serum concentrations of simvastatin and lovastatin and may affect digoxin metabolism.

**Cangrelor**

Cangrelor is a parenteral reversible inhibitor of P2Y$_{12}$. When administered intravenously as a bolus followed by an infusion, cangrelor inhibits ADP-induced platelet aggregation within minutes, and its effect on platelet aggregation disappears within 1 h of discontinuation of the drug. Cangrelor has a short half-life because it is rapidly dephosphorylated in the circulation to an inactive metabolite.

**Therapeutic Use.** Cangrelor is indicated for reduction in the risk of peri-procedural myocardial infarction, repeat coronary revascularization, and stent thrombosis in patients undergoing percutaneous coronary intervention who have not been treated with an oral P2Y$_{12}$ inhibitor and are not given a glycoprotein IIb/IIIa antagonist (Keating et al., 2015).

**Adverse Effects.** The risk of bleeding with cangrelor is greater than that with clopidogrel during the coronary intervention.

**Drug Interactions.** Co-administered clopidogrel or prasugrel will have no antiplatelet effect. Administration of ticagrelor, prasugrel, or clopidogrel should be delayed until the cangrelor infusion is stopped.

**Thrombin Receptor Inhibitor**

There are two major thrombin receptors on the platelet surface, PAR-1 and PAR-4, respectively. Thrombin binds to the G protein–coupled receptors and cleaves them at their amino terminals. The newly created amino terminals then serve as tethered ligands to activate the receptors. PAR-1 is activated by lower concentrations of thrombin than are required to activate PAR-4.

**Vorapaxar**

Vorapaxar is a competitive antagonist of PAR-1 and inhibits thrombin-induced platelet aggregation. The drug is 90% bioavailable and has a rapid onset of action and a circulating half-life of 3 or 4 days. However, because vorapaxar remains tightly bound to PAR-1 on platelets, its effect on thrombin-induced platelet aggregation can persist for up to 4 weeks after the drug is stopped. Vorapaxar is metabolized in the liver by CYP3A4.

**Therapeutic Uses.** Vorapaxar is given orally in combination with either aspirin or clopidogrel. It is indicated for the reduction of thrombotic cardiovascular events in patients with a history of myocardial infarction or peripheral artery disease (Arif et al., 2015; Moschonas et al., 2015).

**Adverse Effects.** Vorapaxar increases the risk of bleeding and is contraindicated in patients with a history of intracranial bleeding, stroke, or transient ischemic attack.

**Drug Interactions.** Potent CYP3A4 inducers, such as rifampin, reduce drug exposure, while strong CYP3A4 inhibitors, such as ketoconazole, increase drug exposure. Antacids and pantoprazole reduce drug exposure.

**Glycoprotein IIb/IIIa Inhibitors**

Glycoprotein IIb/IIIa is a platelet-surface integrin, designated α$_{IIb}$β$_{3}$, by the integrin nomenclature. This dimeric glycoprotein undergoes a conformational transformation when platelets are activated to serve as a receptor for fibrinogen and von Willebrand factor, which anchor platelets to each other, thereby mediating aggregation (Figure 32-1). Thus, inhibitors of this receptor are potent antiplatelet agents that act by a mechanism distinct from that of aspirin or P2Y$_{12}$, or PAR-1 inhibitors. Three agents are approved for use at present; their features are highlighted in Table 32–4. The use of these agents has decreased with the availability of potent P2Y$_{12}$ inhibitors such as prasugrel and ticagrelor.

**Abciximab**

Abciximab is the Fab fragment of a humanized monoclonal antibody directed against the α$_{IIb}$β$_{3}$ receptor. It also binds to the vintorectin receptor on platelets, vascular endothelial cells, and smooth muscle cells. The antibody is administered to patients undergoing percutaneous coronary intervention and, when used in conjunction with aspirin and heparin, has been shown to prevent recurrent myocardial infarction and death (Gara et al., 2013; Roffi et al., 2015). The t$_{1/2}$ of the circulating antibody is about 30 min, but antibody remains bound to the α$_{IIb}$β$_{3}$ receptor and inhibits platelet aggregation as measured in vitro for 18–24 h after infusion. It is given as a 0.25-mg/kg bolus followed by an infusion of 0.125 μg/kg/min (maximum 10 μg/kg/min) for 12 to 24 h.

**Adverse Effects.** The major side effect of abciximab is bleeding, and the contraindications to its use are similar to those for the fibrinolytic agents listed in Table 32–4. The frequency of major hemorrhage in clinical trials varies from 1% to 10%, depending on the intensity of concomitant anticoagulation with heparin. Thrombocytopenia with a platelet count below 50,000 occurs in about 2% of patients and may be due to the formation of antibodies directed against neoepitopes induced by bound antibody. Because the duration of action is long, if major bleeding occurs, platelet transfusion may reverse the aggregation defect because free antibody concentrations fall rapidly after cessation of infusion.

**Eptifibatide**

Eptifibatide is a cyclic peptide inhibitor of the fibrinogen binding site on α$_{IIb}$β$_{3}$. It is administered intravenously and blocks platelet aggregation. In patients undergoing percutaneous coronary intervention,

epitifibatide is typically given as a double intravenous bolus of 180 μg/kg (spaced 10 min apart), followed by an infusion of 2 μg/kg/min for 18 to 24 h. The drug is cleared by the kidneys and has a short plasma half-life of 10 to 15 min. Like abciximab, epitifibatide is mainly used in patients undergoing primary percutaneous coronary intervention for acute ST-segment elevation myocardial infarction, although it also can be used in patients with unstable angina.

**Adverse Effects.** The major side effect is bleeding. Thrombocytopenia occurs in 0.5%–1% of patients and is less frequent than with abciximab.

**Tirofiban**

Tirofiban is an intravenously administered nonpeptide, small-molecule inhibitor of αIIbβ3. It has a short duration of action and is used for management of patients with non-ST-segment elevation acute coronary syndrome. Tirofiban is administered as an intravenously bolus of 25 μg/kg followed by an infusion of 0.15 μg/kg/min for up to 18 h. The infusion dose is reduced by half in patients with a creatinine clearance below 60 mL/min. Like the other agents in this class, the major side effect of tirofiban is bleeding, and it may induce thrombocytopenia.

### The Role of Vitamin K

Green plants are a nutritional source of vitamin K for humans, in whom vitamin K is an essential cofactor in the γ-carboxylation of multiple glutamate residues of several clotting factors and anticoagulant proteins. The vitamin K–dependent formation of Gla residues permits the appropriate interactions of clotting factors, Ca2+, and membrane phospholipids and modulator proteins (see Figures 32–1, 32–2, and 32–3). Vitamin K antagonists (coumarin derivatives) block Gla formation and thereby inhibit clotting; excess vitamin K can reverse the effects.

Vitamin K activity is associated with at least two distinct natural substances, designated as vitamin K1 and vitamin K2. Vitamin K1, or **phytonadione** (also referred to as **phyloquinone**), is 2-methyl-3-phyltyl-1,4-naphthoquinone; it is found in plants and is the only natural vitamin K available for therapeutic use. Vitamin K1 actually is a series of compounds (the **menaquinones**) in which the phyltyl side chain of phytonadione has been replaced by a side chain built up of 2–13 prenyl units. Considerable synthetic of menaquinones occurs in gram-positive bacteria; indeed, intestinal flora synthesizes the large amounts of vitamin K contained in human and animal feces. Menadione is at least as active on a molar basis as phytonadione.

#### Physiological Functions and Pharmacological Actions

Phytonadione and menaquinones promote the biosynthesis of the clotting factors II (prothrombin), VII, IX, and X as well as the anticoagulant proteins C and S and protein Z (a cofactor to the inhibitor of Xa).

Figure 32–6 summarizes the coupling of the vitamin K cycle with glutamate carboxylation. The γ-glutamyl carboxylase and epoxide reductase are integral membrane proteins of the endoplasmic reticulum and function as a multicomponent complex. With respect to proteins affecting blood coagulation, these reactions occur in the liver, but γ-carboxylation of glutamate also occurs in lung, bone, and other cell types. Mutations in γ-glutamyl carboxylase lead to bleeding disorders.

#### Human Requirements

In patients rendered vitamin K deficient by a starvation diet and antibiotic therapy for 3–4 weeks, the minimum daily requirement is estimated to be 0.03 μg/kg of body weight and possibly as high as 1 μg/kg, which is approximately the recommended intake for adults (70 μg/d).

#### Symptoms of Deficiency

The major clinical manifestation of vitamin K deficiency is bleeding. Ecchymoses, epistaxis, hematuria, GI bleeding, and postoperative hemorrhage are common; intracranial hemorrhage may occur. Hemoysis is uncommon. The presence of vitamin K–dependent proteins in bone such as osteocalcin and matrix Gla protein may explain why fetal bone abnormalities can occur with maternal warfarin administration in the first trimester of pregnancy. Vitamin K plays a role in adult skeletal maintenance and the prevention of osteoporosis. Low concentrations of the vitamin are associated with decreased bone mineral density and subsequent fractures; vitamin K supplementation increases the carboxylation state of osteocalcin and improves bone mineral density, but the relationship between these effects is unclear. Bone mineral density in adults does not appear to be changed with long-term warfarin therapy, but new bone formation may be affected.

#### Toxicity

Phytonadione and the menaquinones are nontoxic. Menadione and its derivatives (synthetic forms of vitamin K) may produce hemolytic anemia and kernicterus in neonates and should not be used as therapeutic forms of vitamin K.

#### ADME

The mechanism of intestinal absorption of compounds with vitamin K activity varies depending on their solubility. In the presence of bile salts, phytonadione and the menaquinones are adequately absorbed from the intestine, phytonadione by an energy-dependent, saturable process in proximal portions of the small intestine and menaquinones by diffusion in the distal small intestine and the colon. After absorption, phytonadione is incorporated into chylomicrons in close association with triglycerides and lipoproteins. The low phytonadione levels in newborns may partly reflect the slow plasma lipoprotein concentrations at birth and may lead to an underestimation of vitamin K tissue stores. After absorption, phytonadione and menaquinones are concentrated in the liver, but the concentration of phytonadione declines rapidly. Menaquinones, produced in the distal bowel, are less biologically active because of their long side chain. Very little vitamin K accumulates in other tissues. There is only modest storage of vitamin K in the body. Consequently, when lack of bile interferes with absorption of vitamin K, there is progressive reduction in the levels of the vitamin K–dependent clotting factors over the course of several weeks.

#### Therapeutic Uses

Vitamin K is used therapeutically to correct the bleeding tendency or hemorrhage associated with its deficiency. Vitamin K deficiency can result from inadequate intake, absorption, or utilization of the vitamin or as a consequence of the action of warfarin.

Phytonadione is available in tablet form and in a dispersion with buffered polysorbate and propylene glycol or polyoxyethylated fatty acid derivatives and dextrose. Phytonadione may be given by any route; however, the subcutaneous route should be avoided in patients with a coagulopathy because of the risk of bleeding. The oral route is preferred, but if more rapid reversal is required, phytonadione can be given by slow intravenous infusion; it should not be given rapidly because severe reactions resembling anaphylaxis can occur.

#### Inadequate Intake

After infancy, hypoprothrombinemia due to dietary deficiency of vitamin K is extremely rare. The vitamin is present in many foods and is synthesized by intestinal bacteria. Occasionally, the use of a broad-spectrum antibiotic may itself produce hypoprothrombinemia that responds readily to small doses of vitamin K and reestablishment of normal bowel flora. Hypoprothrombinemia can occur in patients receiving prolonged intravenous alimentation; to prevent this, it is recommended that such patients receive 1 mg of phytonadione per week (the equivalent of about 150 μg/day).
**Hypoprothrombinemia of the Newborn**
Healthy newborn infants have decreased plasma concentrations of vitamin K–dependent clotting factors for a few days after birth, the time required for adequate dietary intake of the vitamin and for establishment of normal intestinal flora. Measurements of non-γ-carboxylated prothrombin suggest that vitamin K deficiency occurs in about 3% of live births. Hemorrhagic disease of the newborn has been associated with breastfeeding; human milk has low concentrations of vitamin K. In addition, the microbiome of breast-fed infants may lack microorganisms that synthesize the vitamin. Commercial infant formulas are supplemented with vitamin K. In the neonate with hemorrhagic disease of the newborn, administration of vitamin K raises the concentration of these clotting factors to levels normal for newborns and controls the bleeding tendency within about 6 h. Routine administration of 1 mg phytonadione intramuscularly at birth is required by law in the U.S. The dose may have to be increased or repeated if the mother has received warfarin or anticonvulsant drug therapy or if the infant develops a bleeding diathesis. Alternatively, some clinicians treat mothers who are receiving anticonvulsants with oral vitamin K prior to delivery (20 mg/d for 2 weeks).

**Inadequate Absorption**
Vitamin K is poorly absorbed in the absence of bile. Thus, hypoprothrombinemia may be associated with intrahepatic or extrahepatic biliary obstruction or with defective intestinal absorption of fat from other causes.

**Biliary Obstruction or Fistula**
Bleeding that accompanies obstructive jaundice or a biliary fistula responds promptly to the administration of vitamin K. Oral phytonadione administered with bile salts is both safe and effective and should be used in the care of the jaundiced patient, both preoperatively and postoperatively. In the absence of significant hepatocellular disease, the prothrombin level rapidly returns to normal. If oral administration is not feasible, a parenteral preparation should be used. The usual daily dose of vitamin K is 10 mg.

**Malabsorption Syndromes**
Among the disorders that result in inadequate absorption of vitamin K from the intestinal tract are cystic fibrosis, celiac disease, Crohn disease, ulcerative colitis, dysentery, and extensive resection of bowel. Because drugs that reduce the bacterial population of the bowel are used frequently in many of these disorders, the availability of the vitamin may be further reduced. For immediate correction of the deficiency, parenteral vitamin K should be given.

**Inadequate Utilization**
Hepatocellular disease or long-standing biliary obstruction may be accompanied or followed by hypoprothrombinemia. If inadequate secretion of bile salts is contributing to the syndrome, some benefit may be obtained from the parenteral administration of 10 mg of phytonadione daily. Paradoxically, administration of large doses of vitamin K or its analogues in an attempt to correct the hypoprothrombinemia can be associated with severe hepatitis or cirrhosis, which may contribute to a further reduction in the level of prothrombin.

**Drug- and Venom-Induced Hypoprothrombinemia**
Warfarin and its congeners act as competitive antagonists of vitamin K and interfere with the hepatic biosynthesis of Gla-containing clotting factors. The treatment of bleeding caused by oral anticoagulants was described previously. Vitamin K may be of help in combating the bleeding and hypoprothrombinemia that follow the bite of the tropical American pit viper or other species whose venom degrades or inactivates prothrombin.

## Vitamin K Antagonist

| Warfarin | • Treatment of venous thromboembolism in tandem with parenteral anticoagulation  
|          | • Secondary prevention of venous thromboembolism  
|          | • Prevention of stroke in atrial fibrillation  
|          | • Prevention of stroke in patient with mechanical heart valves or ventricular assist devices  
|          | • Oral vitamin K antagonist  
|          | • Narrow therapeutic index  
|          | • Requires regular INR monitoring  
|          | • Multiple drug interactions  
|          | • Dietary vitamin K interactions  
|          | • Can be used in renal failure  
|          | • Contraindicated in pregnancy  |

## Direct Oral Thrombin Inhibitor

| Dabigatran etexilate | • Treatment of acute venous thromboembolism after at least 5 days of parenteral anticoagulation  
|                      | • Secondary prevention of venous thromboembolism  
|                      | • Prevention of stroke in atrial fibrillation  
|                      | • Thromboprophylaxis after hip or knee arthroplasty  
|                      | • Fixed twice-daily oral dosing (once daily if used for thromboprophylaxis)  
|                      | • Reduce the dose with CrCL 15–30 mL/min  
|                      | • Contraindicated if CrCL < 15 mL/min  
|                      | • Use with caution in patients with recent bleeding, especially GI bleeding  
|                      | • Can be reversed with idarucizumab  |

## Direct Oral Factor Xa Inhibitors

| Rivaroxaban | • Treatment of acute venous thromboembolism  
|             | • Secondary prevention of venous thromboembolism  
|             | • Prevention of stroke in atrial fibrillation  
|             | • Thromboprophylaxis after hip or knee arthroplasty  
|             | • Prevention of recurrent ischemia in stabilized acute coronary syndrome patients (not in North America)  
|             | • Fixed oral dosing (once daily with the exception of initial treatment of venous thromboembolism, which starts with twice-daily dosing for 21 days and once daily thereafter, or secondary prevention after acute coronary syndrome where the drug is given twice daily)  
|             | • Avoid in patients with renal/hepatic dysfunction  
|             | • Use with caution in patients with recent bleeding, especially GI bleeding  |

## Fibrinolytic Drugs

| Alteplase | • Thrombolysis in acute ischemic stroke, massive pulmonary embolism, or myocardial infarction  
|           | • IV bolus followed by an infusion  
|           | • Risk of major bleeding, including intracranial bleeding  |

| Retepase | • Thrombolysis in myocardial infarction  
|          | • Two IV boluses  
|          | • Risk of major bleeding, including intracranial bleeding  |

| Tenecteplase | • Thrombolysis in pulmonary embolism and myocardial infarction  
|             | • Single IV bolus  
|             | • Risk of major bleeding, including intracranial bleeding  |

## Inhibitors of Fibrinolysis

| Epsilon-aminocaproic acid | • Reduce intraoperative bleeding  
|                           | • Inhibits plasmin-mediated degradation of fibrin  
|                           | • IV infusion  |

| Tranexamic acid | • Major head injury  
|                | • Major trauma resuscitation  
|                | • Reduce intraoperative bleeding  
|                | • Topical application for dental bleeding and epistaxis  
|                | • Menorrhagia  
|                | • Inhibits plasmin-mediated degradation of fibrin  
|                | • Available in oral or IV form  
|                | • Given orally in patients undergoing dental procedures or in women with menorrhagia and IV in patients with major trauma or undergoing major orthopedic surgery  |

### Bibliography

Dyslipidemia is a major cause of ASCVDs, such as CHD, ischemic cerebrovascular disease, and peripheral vascular disease. Cardiovascular disease represents the number one cause of death among adults in many developed nations (Mozaffarian et al., 2015). Both genetic disorders and lifestyle contribute to the dyslipidemias, including hypercholesterolemia and low levels of HDL-C.

Classes of drugs that modify cholesterol levels include the following:

- Inhibitors of HMG-CoA reductase (statins)
- Bile acid-binding resins
- Nicotinic acid (niacin)
- Fibric acid derivatives (fibrates)
- Inhibitor of cholesterol absorption (ezetimibe)
- Omega-3 fatty acid ethyl esters (fish oil)
- PCSK9 inhibitors
- MTP inhibitor (lomitapide)
- Inhibitor of apolipoprotein B-100 synthesis ( mipomersen )

The 2014 ACC/AHA Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults (Stone et al., 2014) recommends a substantial shift in approach to cholesterol management compared to the ATPIII (Grundy et al., 2004; NCEP, 2002). Whereas ATPIII advocated treating to specific lipoprotein targets, the 2014 ACC/AHA guideline focuses on offering fixed doses of statins to patients in four statin benefit groups to reduce morbidity and mortality. Since the 2014 release of the ACC/AHA guideline, several additional expert consensus recommendations have been published, providing alternative opinions on cholesterol management (Jacobson et al., 2015) and recommendations regarding the role of nonstatin cholesterol treatments (Lloyd-Jones et al., 2016) in reduction of ASCVD risk (see Table 33–1).

### Plasma Lipoprotein Metabolism

Lipoproteins are macromolecular assemblies that contain lipids and proteins. The lipid constituents include free and esterified cholesterol, triglycerides, and phospholipids. The protein components, known as apolipoproteins or apoproteins, provide structural stability to the lipoproteins and also may function as ligands in lipoprotein-receptor interactions or as cofactors in enzymatic processes that regulate lipoprotein metabolism. The major classes of lipoproteins and their properties are summarized in Table 33–2. Apoproteins have well-defined roles in plasma lipoprotein metabolism (Table 33–3). Mutations in lipoproteins or their receptors can lead to familial dyslipidemias and premature death due to accelerated atherosclerosis.

In all spherical lipoproteins, the most water-insoluble lipids (cholesterol esters and triglycerides) are core components, and the more polar, water-soluble components (apolipoproteins, phospholipids, and unesterified cholesterol) are located on the surface. Except for apo(a), the lipid-binding regions of all apoproteins contain amphipathic helices that interact with the polar, hydrophilic lipids (such as surface phospholipids) and with the aqueous plasma environment in which the lipoproteins circulate. Differences in the non–lipid-binding regions determine the functional specificities of the apolipoproteins.

Figure 33–1 summarizes the pathways involved in the uptake and transport of dietary fat and cholesterol, pathways that involve the lipoprotein structures described next.

#### Chylomicrons

Chylomicrons are synthesized from the fatty acids of dietary triglycerides and cholesterol absorbed by epithelial cells in the small intestine. Chylomicrons are the largest and lowest-density plasma lipoproteins. In normolipemic individuals, chylomicrons are present in plasma for 3–6 h after a fat-containing meal has been ingested. Intestinal cholesterol absorption is mediated by NPC1L1, which appears to be the target of ezetimibe, a cholesterol absorption inhibitor.

After their synthesis in the endoplasmic reticulum, triglycerides are transferred by MTP to the site where newly synthesized apo B-48 is available to form chylomicrons. Apo B-48, synthesized only by intestinal epithelial cells, is unique to chylomicrons and functions primarily as a structural component of chylomicrons. Dietary cholesterol is esterified by the ACAT-2. ACAT-2 is found in the intestine and in the liver, where cellular free cholesterol is esterified before triglyceride-rich lipoproteins (chylomicrons and VLDLs) are assembled.

After entering the circulation via the thoracic duct, chylomicrons are metabolized initially at the capillary luminal surface of tissues that synthesize LPL (see Figure 33–1), including adipose tissue, skeletal and cardiac muscle, and breast tissue of lactating women. The resulting free fatty acids are taken up and used by the adjacent tissues. The interaction of chylomicrons and LPL requires apo C-II as a cofactor.
CHAPTER 33
DRUG THERAPY FOR DYSLIPIDEMIAS

Abbreviations

ACAT-2: type 2 isozyme of acyl coenzyme A:cholesterol acyltransferase
ACC: American College of Cardiology
AHA: American Heart Association
ALT: alanine aminotransferase
apo(a): apolipoprotein (a)
ASCVD: atherosclerotic cardiovascular disease
AST: aspartate aminotransferase
CETP: cholesteryl ester transfer protein
CHD: coronary heart disease
DHA: docosahexaenoic acid
DM: diabetes mellitus
EPA: eicosapentaenoic acid
ER: extended release
FH: familial hypercholesterolemia
FRS: Framingham Heart Study
HDL: high-density lipoprotein
HDL-C: high-density lipoprotein cholesterol
heFH: heterozygous familial hypercholesterolemia
HL: hepatic lipase
HMGC-CoA: 3-hydroxy-3-methylglutaryl coenzyme A
hoFH: homozygous familial hypercholesterolemia
HSL: hormone-sensitive lipase
IDL: intermediate-density lipoprotein
LCAT: lecithin:cholesterol acyltransferase
LDL: low-density lipoprotein
LDL-C: low-density lipoprotein cholesterol
LDLR: LDL receptor
LP(a): lipoprotein (a)
LPL: lipoprotein lipase
LRP: LDL receptor–related protein
MTP: microsomal triglyceride transfer protein
NCEP: National Cholesterol Education Program
NHLBI: National Heart, Lung, and Blood Institute
NLA: National Lipid Association
NPC1L1: Niemann-Pick C1–like 1 protein
OTC: over the counter
PCE: pooled cohort equation
PCSK9: proprotein convertase subtilisin/kexin type 9
PPAR: peroxisome proliferator–activated receptor
SR: scavenger receptor
SREBP: sterol regulatory element–binding protein
USPSTF: U.S. Preventive Services Task Force
VLDL: very low-density lipoprotein

Chylomicron Remnants

After LPL-mediated removal of much of the dietary triglycerides, the chylomicron remnants, with all of the dietary cholesterol, detach from the capillary surface and within minutes are removed from the circulation by the liver (see Figure 33–1). First, the remnants are sequestered by the interaction of apo E with hepatic sulfate proteoglycans on the surface of hepatocytes and are processed by HL, further reducing the remnant triglyceride content. Next, apo E mediates remnant uptake by interacting with the hepatic LDL receptor or the LRP.

During the initial hydrolysis of chylomicron triglycerides by LPL, apo A-I and phospholipids are shed from the surface of chylomicrons and remain in the plasma. This is one mechanism by which nascent (precursor) HDL are generated. Chylomicron remnants are not precursors of LDL, but the dietary cholesterol delivered to the liver by remnants increases plasma LDL levels by reducing LDL receptor–mediated catabolism of LDL by the liver.

Very Low-Density Lipoproteins

The VLDLs are produced in the liver when triglyceride production is stimulated by an increased flux of free fatty acids or by increased de novo synthesis of fatty acids by the liver. Apo B-100, apo E, and apo C-I, C-II, and C-III are synthesized constitutively by the liver and incorporated into VLDLs (see Table 33–3). Triglycerides are synthesized in the endoplasmic reticulum, and along with other lipid constituents, are transferred by MTP to the site in the endoplasmic reticulum where newly synthesized apo B-100 is available to form nascent (precursor) VLDL. Small amounts of apo E and the C apoproteins are incorporated into nascent particles within the liver before secretion, but most of these apoproteins are acquired from plasma HDL after the VLDLs are secreted by the liver. Mutations of MTP that result in the inability of triglycerides to be transferred to either apo B-100 in the liver or apo B-48 in the intestine prevent VLDL and chylomicron production and cause the genetic disorder abetalipoproteinemia.

Plasma VLDL is catabolized by LPL in the capillary beds in a process similar to the lipolytic processing of chylomicrons (see Figure 33–1). When triglyceride hydrolysis is nearly complete, the VLDL remnants, usually termed IDLs, are released from the capillary endothelium and reenter the circulation. Apo B-100–containing small VLDLs and IDLs, which have a t½ of less than 30 min, have two potential fates. About 40%–60% are cleared from the plasma by the liver via apo B-100– and apo E–mediated interaction with LDL receptors and LRP. LPL, HL, and heFH convert the remainder of the IDLs to LDLs by removal of additional triglycerides. The C apoproteins, apo E, and apo A-V redistribute to HDL.

Low-Density Lipoproteins

Virtually all of the LDL particles in the circulation are derived from VLDL. The LDL particles have a t½ of 1.5–2 days. In subjects without

Figure 33–1 The major pathways involved in the metabolism of chylomicrons synthesized by the intestine and VLDL synthesized by the liver. Chylomicrons are converted to chylomicron remnants by the hydrolysis of their triglycerides by LPL. Chylomicron remnants are rapidly cleared from the plasma by the liver. “Remnant receptors” include the LRP, LDL receptors, and perhaps other receptors. FFA released by LPL is used by muscle tissue as an energy source or taken up and stored by adipose tissue.
hypertriglyceridemia, two-thirds of plasma cholesterol is found in the LDL. Plasma clearance of LDL is mediated primarily by LDL receptors (apo B-100 binds LDL to its receptor); a small component is mediated by non-receptor clearance mechanisms.

The most common cause of autosomal dominant hypercholesterolemia involves mutations of the LDL receptor gene. Defective or absent LDL receptors cause high levels of plasma LDL and FH. Treatment of FH, which is associated with accelerated ASCVD and premature death at the age of 30 or before, is treated by inhibiting apo B-100 synthesis with mipomersen, as well as by inhibiting cholesterol synthesis with statins. LDL becomes atherogenic when modified by oxidation, a required step for LDL uptake by the SRs of macrophages. This process leads to foam cell formation in arterial lesions. At least two SRs are involved (SR-AI/II and CD36). SR-AI/II appears to be expressed more in early atherogenesis, and CD36 expression in arterial lesions. At least two SRs are involved (SR-AI/II and CD36).

The liver expresses a large complement of LDL receptors and removes about 75% of all LDL from the plasma. Consequently, manipulation of hepatic LDL receptor gene expression is a most effective way to modulate plasma LDL-C levels. The most effective dietary alteration (decreased consumption of saturated fat and cholesterol) and pharmacological treatment (statins) for hypercholesterolemia act by enhancing hepatic LDL receptor expression.

High-Density Lipoproteins

The HDLs are protective lipoproteins that decrease the risk of CHD; thus, high levels of HDL are desirable. This protective effect may result from the participation of HDL in reverse cholesterol transport, the process by which excess cholesterol is acquired from cells and transferred to the liver for excretion. HDL also affects other anti-inflammatory, antioxidant, platelet antiaggregatory, anticoagulant, and probrinolytic activities. Apo A-I is the major HDL apoprotein and its plasma concentration is a more powerful inverse predictor of CHD risk than is the HDL-C level. Apo A-I synthesis is required for normal production of HDL.

Mutations in the apo A-I gene that cause HDL deficiency often are associated with accelerated atherogenesis. In addition, two major subclasses of mature HDL particles in the plasma can be differentiated by their content of the major HDL apoproteins, apo A-I and apo A-II. Epidemiologic evidence in humans suggests that apo A-II may be atheroprotective.

The membrane transporter ABCA1 facilitates the transfer of free cholesterol from cells to HDL. After free cholesterol is acquired by the preβ1 HDL, it is esterified by LCAT. The newly esterified and nonpolar cholesterol moves into the core of the particle, which becomes progressively more spherical, larger, and less dense with continued cholesterol acquisition and esterification. As the cholesteryl ester content of the particle (now called HDL2) increases, the cholesteryl esters of these particles begin to be exchanged for triglycerides derived from any of the triglyceride-containing lipoproteins (chylomicrons, VLDLs, remnant lipoproteins, and LDLs.

This exchange, mediated by the CETP, accounts for the removal of about two-thirds of the cholesterol associated with HDL in humans. The transferred cholesterol subsequently is metabolized as part of the lipoprotein into which it was transferred. Treatments that target CETP and the ABC transporters have yielded equivocal results in humans. While CETP inhibitors effectively reduce LDL, they also paradoxically increase the frequency of adverse cardiovascular events (angina, revascularization, myocardial infarction, heart failure, and death).

The triglyceride that is transferred into HDL, is hydrolyzed in the liver by HL, a process that regenerates smaller, spherical HDL3 particles that recirculate and acquire additional free cholesterol from tissues containing excess free cholesterol. HL activity is regulated and modulates HDL-C levels. Androgens increase HL gene expression/activity, which accounts for the lower HDL-C values observed in men than in women. Estrogens reduce HL activity, but their impact on HDL-C levels in women is substantially less than that of androgens on HDL-C levels in men. HL appears to have a pivotal role in regulating HDL-C levels, as HL activity is increased in many patients with low HDL-C levels.

Lipoprotein (a)

Lipoprotein (a) [Lp(a)] is composed of an LDL particle that has a second apoprotein, apo(a), in addition to apo B-100. Apo(a) of Lp(a) is structurally related to plasminogen and appears to be atherogenic.

Atherosclerotic Cardiovascular Disease Risk Assessment

Therapy for dyslipidemias is based on reducing the risk of fatal and nonfatal atherosclerotic cardiovascular events, including myocardial infarction and stroke. A flowchart that illustrates the assessment and management of ASCVD risk is shown in Figure 33–2.

The major conventional risk factors for ASCVD are elevated LDL-C, reduced HDL-C, cigarette smoking, hypertension, type 2 diabetes mellitus, advancing age, and a family history of premature CHD events (men < 55 years; women < 65 years) in a first-degree relative (Table 33–4).

Primary prevention involves management of risk factors to prevent a first-ever ASCVD event. Secondary prevention is aimed at patients who have had a prior ASCVD event (myocardial infarction, stroke, or revascularization) and whose risk factors must be treated aggressively. In addition to cholesterol management, a comprehensive approach to ASCVD risk reduction includes smoking cessation, weight management, physical activity, healthy eating habits, antplatelet use, and glucose and blood pressure management. All treatment plans to reduce ASCVD risk must include patient counseling to effect lifestyle changes. Secondary causes of dyslipidemias (Table 33–5), including medications that affect cholesterol, should also be considered prior to initiating treatment. Patients should also be evaluated for metabolic syndrome, which affects more than one in three adults and includes insulin resistance, obesity, hypertension, low HDL-C levels, a procoagulant state, vascular inflammation, and substantially increased risk of cardiovascular disease.

The PCE, published as part of the 2014 ACC/AHA guideline on the assessment of cardiovascular risk, was developed based on data from nine NHLBI-funded cohort studies and included data from geographically and racially diverse patient populations. The PCE estimates an individual patient's 10-year risk of ASCVD (defined as nonfatal myocardial infarction,
CHD death, or fatal or nonfatal stroke) based on age, gender, total cholesterol, HDL-C, race, systolic blood pressure, smoking status, and history of diabetes, and hypertension. The ASCVD risk assessment calculator using the PCE is available online (https://tools.acc.org/ASCVD-Risk-Estimator/) and as a mobile app. Cardiovascular risk assessment calculators have also been developed for lifetime risk of cardiovascular disease.

**Statin Drug Therapy**

Although an understanding of optimal lipoprotein levels is helpful (see ranges in Table 33–6), the 2014 ACC/AHA guideline recommends the use of fixed statin doses for at-risk patients, instead of titration to specific lipoprotein goals. The ACC/AHA guidelines identify four statin benefit groups or patient populations most likely to benefit from statin therapy:

**TABLE 33–4 RISK FACTORS FOR ATHEROSCLEROTIC CARDIOVASCULAR DISEASE**

</tr>
</tbody>
</table>

**Current cigarette smoking**

Defined as smoking within the preceding 30 days

**Hypertension**

Systolic blood pressure ≥ 140, diastolic pressure ≥ 90 or use of antihypertensive medication, irrespective of blood pressure

**Low HDL-C**

< 40 mg/dL (consider < 50 mg/dL as “low” for women)

**Obesity**

Body mass index > 25 kg/m² and waist circumference > 40 inches (men) or > 35 inches (women)

**Type 2 diabetes mellitus**

*CHD defined as myocardial infarction, coronary death, or a coronary revascularization procedure.

*Diabetes mellitus is considered a high or very high risk condition for ASCVD.

*Data from 2015 NLA recommendations, part 1 (Jacobson et al. 2015).

Patients with known history of clinical ASCVD and those with elevated LDL-C greater than or equal to 190 mg/dL should be offered statins.

For primary prevention in patients 40 through 79 years of age with LDL 70 to 189 mg/dL, use of the PCE is recommended to identify patients more likely to benefit from treatment. Table 33–1 summarizes ACC/AHA recommendations for use of statins in adults. In November 2016, the USPSTF released recommendations for the use of statins in primary prevention populations (USPSTF, 2016). These recommendations build on those in the ACC/AHA guideline in helping to further identify higher-risk primary prevention patients. USPSTF also questions the use of higher-intensity statins in the 2014 ACC/AHA guideline and instead recommends low- to moderate-intensity statins for primary prevention patients.

Because the overwhelming body of evidence for ASCVD risk reduction with lipid-lowering therapies is from statin trials, evidence-based statin therapy of appropriate intensity is the hallmark of drug therapy of dyslipidemias. These drugs are competitive inhibitors of HMG-CoA reductase, which catalyzes an early, rate-limiting step in cholesterol biosynthesis. Higher doses of the more potent statins (e.g., atorvastatin, simvastatin, and rosuvastatin) also can reduce triglyceride levels caused by elevated VLDL levels. Figure 33–3 shows a representative statin structure and the reaction catalyzed by HMG-CoA reductase.

**Mechanism of Action**

Statins exert their major effect—reduction of LDL levels—through a mevalonic acid–like moiety that competitively inhibits HMG-CoA reductase. By reducing the conversion of HMG-CoA to mevalonate, statins inhibit an early and rate-limiting step in cholesterol biosynthesis. Statins affect blood cholesterol levels by inhibiting hepatic cholesterol synthesis, which results in increased expression of the LDL receptor gene. Some studies suggested that statins also can reduce LDL levels by enhancing the removal of LDL precursors (VLDL and IDL) and by decreasing hepatic VLDL production. The reduction in hepatic VLDL production induced by statins is thought to be mediated by reduced synthesis of cholesterol, a required component of VLDLs.

**ADME**

After oral administration, intestinal absorption of the statins is variable (30%–85%). All the statins, except simvastatin and lovastatin, are administered in the β-hydroxy acid form, which is the form that inhibits HMG-CoA reductase. Simvastatin and lovastatin are administered as inactive lactones that must be transformed in the liver to their respective β-hydroxy acids, simvastatin acid, and lovastatin acid. There is extensive first-pass hepatic uptake of all statins, mediated primarily by the organic transporters.
anion transporter OATP1B1 (see Chapter 5). **Hepatic cholesterol synthesis** is maximal between midnight and 2:00 a.m. Thus, statins with \( t_{1/2} \) of 4 h or less (all but atorvastatin and rosuvastatin) should be taken in the evening. Atorvastatin and rosuvastatin both have longer half-lives and may be taken at other times of day to optimize adherence.

**TABLE 33–6 CLASSIFICATION OF PLASMA LIPID LEVELS (mg/dL)**

| Non-HDL-C | | |
|<130 | Desirable | |
|130–159 | Above desirable | |
|160–189 | Borderline high | |
|190–219 | High | |
|\( \geq 220 \) | Very high | |
|HDL-C | | |
|<40 | Low (consider < 50 mg/dL as low for women) | |
|>60 | High (desirable because of negative risk) | |
|LDL-C | | |
|<70 | Optimal for very high risk\(^\ast\) | |
|<100 | Desirable | |
|100–129 | Above desirable | |
|130–159 | Borderline high | |
|160–189 | High | |
|\( \geq 190 \) | Very high | |
|Triglycerides | | |
|<150 | Normal | |
|150–199 | Borderline high | |
|200–499 | High | |
|\( \geq 500 \) | Very high | |

Due to extensive first-pass hepatic uptake, systemic bioavailability of the statins and their hepatic metabolites varies between 5% and 30% of administered doses. The metabolites of all statins, except fluvastatin and pravastatin, have some HMG-CoA reductase inhibitory activity. Under steady-state conditions, small amounts of the parent drug and its metabolites produced in the liver can be found in the systemic circulation. In the plasma, more than 95% of statins and their metabolites are protein bound, with the exception of pravastatin and its metabolites, which are only 50% bound. Peak plasma concentrations of statins are achieved in 1–4 h. The \( t_{1/2} \) of the parent compounds are 1–4 h, except in the case of atorvastatin and rosuvastatin, which have half-lives of about 20 h, and simvastatin with a \( t_{1/2} \) of about 12 h. The longer \( t_{1/2} \) of atorvastatin and rosuvastatin may contribute to their greater cholesterol-lowering efficacy. The liver biotransforms all statins, and more than 70% of statin metabolites are excreted by the liver, with subsequent elimination in the feces.

**Therapeutic Effects**

**Triglyceride Reduction by Statins**

Triglyceride levels greater than 250 mg/dL are reduced substantially by statins, and the percentage reduction achieved is similar to the percentage reduction in LDL-C.

**Effect of Statins on HDL-C Levels**

Most studies of patients treated with statins have systematically excluded patients with low HDL-C levels. In studies of patients with elevated LDL-C levels and gender-appropriate HDL-C levels (40–50 mg/dL for men; 50–60 mg/dL for women), an increase in HDL-C of 5%–10% was observed, irrespective of the dose or statin employed. However, in patients with reduced HDL-C levels (<35 mg/dL), statins may differ in their effects on HDL-C levels. More studies are needed to ascertain
whether the effects of statins on HDL-C in patients with low HDL-C levels are clinically significant.

**Effects of Statins on LDL-C Levels**

Dose-response relationships for all statins demonstrate that the efficacy of LDL-C lowering is log linear; LDL-C is reduced by about 6% (from baseline) with each doubling of the dose. Maximal effects on plasma cholesterol levels are achieved within 7–10 days. The statins are effective in almost all patients with high LDL-C levels. The exception is patients with hoFH, who have very attenuated responses to the usual doses of statins because both alleles of the LDL receptor gene code for dysfunctional LDL receptors.

**Adverse Effects and Drug Interactions**

**Hepatotoxicity**

Serious hepatotoxicity is rare and unpredictable, with a rate of about 1 case per million person-years of use. ACC/AHA guidelines recommend measuring ALT at baseline prior to initiation of statins. However since 2012, the FDA has no longer recommended routine monitoring of ALT or other liver enzymes following the initiation of statin therapy because routine periodic monitoring does not appear to be effective in detecting or preventing serious liver injury. Liver enzymes should be evaluated in patients with clinical symptoms suggestive of liver injury following initiation or changes in statin treatment (FDA, 2012).

**Myopathy**

The major adverse effect associated with statin use is myopathy. Myopathy refers to a broad spectrum of muscle complaints, ranging from mild muscle soreness or weakness (myalgia) to life-threatening rhabdomyolysis. The risk of muscle adverse effects increases in proportion to statin dose and plasma concentrations. Consequently, factors inhibiting statin catabolism or interfering with hepatic uptake or preventing serious liver injury. Liver enzymes should be evaluated in patients with clinical symptoms suggestive of liver injury following initiation or changes in statin treatment (FDA, 2012).

**Other Considerations**

The choice of statins should be patient specific and based on factors such as cost, drug interactions, possible adverse effects, and desired intensity. Statin doses are characterized as low, moderate, or high intensity (Table 33–7), based on the degree of LDL-C lowering expected (range 30%–60%).

Rosuvastatin and pravastatin may be better tolerated than other statins and should be considered in patients with a history of myalgias with other statins. Lovastatin absorption is increased when taken with food, and patients should be encouraged to take with their evening meal. According to a 2012 FDA warning, simvastatin should not be used in combination with cyclosporine, HIV protease inhibitors, erythromycin, or gemfibrozil. In patients taking amiodipine or amiodarone, the daily dose of simvastatin should not exceed 20 mg. No more than 10 mg of simvastatin should be used in combination with diitiazem or verapamil. Concerns have been raised about possible cognitive impairment with statins, although review of the published data do not suggest that statins harm cognition. In contrast, other studies suggested statins may have a role in the prevention of dementias. Statins, especially at higher doses, likely confer a small increased risk of developing diabetes. However, the beneficial effects of
CHAPTER 33
DRUG THERAPY FOR DYSLIPIDEMIAS

Bile Acid Sequestrants

**Cholesterol, Colestipol, Colesevelam**

The bile acid sequestrants cholestyramine and colestipol are among the oldest of the hypolipidemic drugs and are probably the safest because they are not absorbed from the intestine. These resins also are recommended for patients 11–20 years of age. Although statins are remarkably effective as monotherapy, the resins could be utilized as a second agent if statin therapy does not lower LDL-C levels sufficiently or in cases of statin intolerance.

**Mechanism of Action.** The bile acid sequestrants are highly positively charged and bind negatively charged bile acids. Because of their large size, the resins are not absorbed, and the bound bile acids are excreted in the stool. Because more than 95% of bile acids are normally reabsorbed, interruption of this process depletes the pool of bile acids, and hepatic bile acid synthesis increases. As a result, hepatic cholesterol content declines, stimulating the production of LDL receptors, an effect similar to that of statins. The increase in hepatic LDL receptors increases LDL clearance and lowers LDL-C levels, but this effect is partially offset by the enhanced cholesterol synthesis caused by upregulation of HMG-CoA reductase. Inhibition of reductase activity by a statin substantially increases the effectiveness of the resins. The resin-induced increase in bile acid production is accompanied by an increase in hepatic triglyceride synthesis, which is of consequence in patients with significant hypertriglyceridemia (baseline triglyceride level > 250 mg/dL). Use of colesevelam to lower LDL-C levels in hypertriglyceridemic patients should be accompanied by frequent (every 1–2 weeks) monitoring of fasting triglyceride levels.

**Effects on Lipoprotein Levels.** The reduction in LDL-C by resins is dose dependent. Doses of 8–12 g of cholestyramine or 10–15 g of colestimol are associated with 12%–18% reductions in LDL-C. Colesevelam lowers LDL-C by 18% at its maximum dose. Maximal doses (24 g of cholestyramine, 30 g of colestimol) may reduce LDL-C by as much as 25% but will cause GI side effects, which are often unacceptable. One to 2 weeks is sufficient to attain maximal LDL-C reduction by a given resin dose. In patients with normal triglyceride levels, triglycerides may increase transiently and then return to baseline. When used with a statin, resins are usually prescribed at submaximal doses due to poor tolerability.

**Preparations and Use.** The powdered forms of cholestyramine (4 g/dose) and colestimol (5 g/dose) are either mixed with a fluid (water or juice) and drunk as a slurry or mixed with crushed ice in a blender. Ideally, patients should take the resins before breakfast and before supper, starting with 1 scoop or packet twice daily and increasing the dosage after several weeks or longer as needed and as tolerated. Patients generally will not take more than 2 doses (scoops or packets) twice daily. Colesevelam hydrochloride is available as a solid tablet containing 0.625 g of colesevelam and as a powder in packets of 3.75 g or 1.875 g. Starting dose is either 3 tablets taken twice daily with meals or all 6 tablets taken with a meal. The tablets should be taken with a liquid. The maximum daily dose is 7 tablets (4.375 g).

**Adverse Effects and Drug Interactions.** The resins are generally safe, as they are not systemically absorbed. Because they are administered as chloride salts, rare instances of hyperchloremic acidosis have been reported. Severe hypertriglyceridemia is a contraindication to the use of cholestyramine and colestimol because these resins increase triglyceride levels. At present, there are insufficient data on the effect of colesevelam on triglyceride levels.

Drinking a slurry of powdered cholestyramine or colestimol produces a gritty sensation that is unpleasant but generally tolerated. Colestimol is available in a tablet form. Colesevelam is available as a combination product that absorbs water and creates a soft, gelatinous material that allegedly minimizes the potential for GI irritation. Patients taking cholestyramine and colestimol complain of bloating and dyspepsia. These symptoms can be substantially reduced if the drug is completely suspended in liquid several hours before ingestion. Constipation may occur but sometimes can be prevented by adequate daily water intake and psyllium. Colesevelam may be less likely than colestimol to cause the dyspepsia, bloating, and constipation.

The effect of cholestyramine and colestimol on the absorption of most drugs has not been studied. Cholestyramine and colestimol bind and interfere with the absorption of many drugs, including some thiazides, furosemide, propranolol, L-thyroxine, digoxin, warfarin, and some of the statins.

**Atravastatin 40–80 mg, Rosuvastatin 20–40 mg**

**Atravastatin 10–20 mg, Fluvastatin 40 mg twice daily, Lovastatin 40 mg, Pitavastatin 2–4 mg, Pravastatin 40–80 mg, Rosuvastatin 5–10 mg, Simvastatin 20–40 mg**

**Fluvastatin 20–40 mg, Lovastatin 20 mg, Pitavastatin 1 mg, Pravastatin 10–20 mg, Simvastatin 10 mg**

Bold type signifies statins and doses used in randomized controlled trials demonstrating a reduction in major cardiovascular events or death.

Source: Data from Table 5 in 2014 ACC/AHA guidelines (Stone et al., 2014) and Table 3 in “2016 ACC Expert Consensus Decision Pathway on the Role of Non-Statin Therapies” (Lloyd-Jones et al., 2016).
Colesevelam does not appear to interfere with the absorption of fat-soluble vitamins or of drugs such as digoxin,Lovastatin,warfarin,metoprolol,quinidine, and valproic acid. Colesevelam reduces the maximum concentration and the area under the curve of sustained-release verapamil by 31% and 11%, respectively. In the absence of information to the contrary, prudence suggests that patients take other medications 1 h before or 3–4 h after a dose of colesevelam or colestipol. The safety and efficacy of colesevelam have not been studied in pediatric patients or pregnant women.

**Niacin (Nicotinic Acid)**

Niacin is a water-soluble B-complex vitamin that functions as a vitamin only after conversion to NAD or NADP, in which it occurs as an amide. Both niacin and its amide are readily absorbed from the small intestine after ingestion. Niacin also is the only lipid-lowering drug that reduces Lp(a) levels significantly. Despite salutary effect on lipids, niacin's side effects limit its use. Concurrent use of niacin and a statin can cause myopathy. Two randomized trials evaluating niacin as add-on therapy to a statin versus statin monotherapy demonstrated no further reduction in ASCVD risk, despite improved lipoprotein parameters. Given this evidence, the FDA removed the indication for niacin use in addition to statin therapy and withdrew approval for statin combination formulations containing niacin (FDA, 2016). Niacin could still be considered as monotherapy in a statin-intolerant patient.

**Mechanism of Action**

In adipose tissue, niacin inhibits the lipolysis of triglycerides by HSL, thereby reducing transport of free fatty acids to the liver and decreasing hepatic triglyceride synthesis. Niacin may exert its effects on lipolysis by stimulating a G protein–coupled receptor (GPR109A) that couples to Gi and inhibits cyclic AMP production in adipocytes. In the liver, niacin reduces triglyceride synthesis by inhibiting both the synthesis and the esterification of fatty acids, effects that increase apo B degradation. Reduction of triglyceride synthesis reduces hepatic VLDL production, which accounts for the reduced LDL-C. Niacin also enhances LPL activity, an action that promotes the clearance of chylomicrons and VLDL triglycerides. Niacin raises HDL-C levels by decreasing the fractional clearance of apo A-I in HDL rather than by enhancing HDL synthesis.

**ADME**

The doses of regular (crystalline) niacin used to treat dyslipidemia are almost completely absorbed, and peak plasma concentrations (up to 0.24 mmol) are achieved within 30–60 min. The t1/2 is about 60 min, which necessitates dosing two to three times daily. At lower doses, most niacin is taken up by the liver; only the major metabolite, nicotinuric acid, is found in the urine. At higher doses, a greater proportion of the drug is excreted in the urine as unchanged nicotinic acid.

**Effects on Plasma Lipoprotein Levels**

Regular or crystalline niacin in doses of 2–6 g/d reduces triglycerides by 35%–50% (as effectively as fibrates and statins); the maximal effect occurs within 4–7 days. Reductions of 25% in LDL-C levels are possible with doses of 4.5–6 g/d; 3–6 weeks are required for maximal effect. Niacin is the most effective agent available for increasing HDL-C (30%–40%), but the effect is less in patients with HDL-C levels less than 35 mg/DL. Niacin also is the only lipid-lowering drug that reduces Lp(a) levels significantly. Despite salutary effect on lipids, niacin's side effects limit its use (see Adverse Effects).

**Therapeutic Use**

Niacin is indicated for hypertriglyceridemia and elevated LDL-C. There are two commonly available forms of niacin. Crystalline niacin (immediate release or regular) refers to niacin tablets that dissolve quickly after ingestion. Sustained-release niacin refers to preparations that continuously release niacin for 6–8 h after ingestion. Niacin ER is the only preparation of niacin that is FDA-approved for treating dyslipidemia and that requires a prescription. Crystalline niacin tablets are available OTC in a variety of strengths, from 50–500 mg tablets. The dose may be increased stepwise every 7 days to a total daily dose of 1.5–2 g. After 2–4 weeks at this dose, transaminases, serum albumin, fasting glucose, and uric acid levels should be measured. After a stable dose is attained, blood should be drawn every 3–6 months to monitor for the various toxicities. OTC, sustained-release niacin preparations, and niacin ER are effective up to a total daily dose of 2 g. All doses of sustained-release niacin, but particularly doses above 2 g/d, have been reported to cause hepatotoxicity, which may occur soon after beginning therapy or after several years of use. The potential for severe liver damage should preclude use of OTC preparations in most patients. Niacin ER may be less likely to cause hepatotoxicity.

**Adverse Effects**

Two of niacin's side effects, flushing and dyspepsia, limit patient compliance. The cutaneous effects include flushing and pruritus of the face and upper trunk, skin rashes, and acanthosis nigricans. Flushing and associated pruritus are prostaglandin-mediated, thus taking an aspirin each day can alleviate the flushing in many patients. Flushing is worse when therapy is initiated or the dosage is increased but ceases in most patients after 1–2 weeks of a stable dose. Flushing is more likely to occur when niacin is consumed with hot beverages or with alcohol. Flushing is minimized if therapy is initiated with low doses (100–250 mg twice daily) and if the drug is taken after a meal. Dry skin, a frequent complaint, can be dealt with by using skin moisturizers, and acanthosis nigricans can be dealt with by using lotions containing salicylic acid. Dyspepsia and rarer episodes of nausea, vomiting, and diarrhea are less likely to occur if the drug is taken after a meal. Patients with any history of peptic ulcer disease should not take niacin.

The most common, medically serious side effects are hepatotoxicity, manifested as elevated serum transaminases, and hyperglycemia. Both regular (crystalline) niacin and sustained-release niacin, which was developed to reduce flushing and itching, have been reported to cause severe liver toxicity. Niacin ER appears to be less likely to cause severe hepatotoxicity, perhaps simply because it is administered once daily. The incidence of flushing and pruritus with this preparation is not substantially different from that with regular niacin. Severe hepatotoxicity is more likely to occur when patients take more than 2 g of sustained-release OTC preparations. Affected patients experience flu-like fatigue and weakness; usually, aspartate transaminase and ALT are elevated, serum albumin levels decline, and total cholesterol and LDL-C levels decline substantially.

In patients with diabetes mellitus, niacin should be used cautiously because niacin-induced insulin resistance can cause severe hyperglycemia. If niacin is prescribed for patients with known or suspected diabetes, blood glucose levels should be monitored at least weekly until proven to be stable. Niacin also elevates uric acid levels and may reactivate gout. A history of gout is a relative contraindication for niacin use. Rarer reversible side effects include toxic amblyopia and toxic maculopathy. Atrial tachyarrhythmias and atrial fibrillation have been reported, more commonly in elderly patients. Niacin, at doses used in humans, has been associated with birth defects in experimental animals and should not be taken by pregnant women.

**Fibric Acid Derivatives**

Clofibrate is a halogenated fibric acid derivative. Gemfibrozil is a nonhalogenated acid that is distinct from the halogenated fibrates. A number of fibric acid analogues (e.g., fenofibrate, bezafibrate, cipofibrate) have been developed and are used in Europe and elsewhere.

**Mechanism of Action**

The mechanisms by which fibrates lower lipoprotein levels, or raise HDL levels, remain unclear. Many of the effects of these compounds on blood
lipids are mediated by their interaction with PPARs, which regulate gene transcription. Fibrates bind to PPARα and reduce triglycerides through PPARα-mediated stimulation of fatty acid oxidation, increased LPL synthesis, and reduced expression of apo C-III. Increased LPL synthesis would enhance the clearance of triglyceride-rich lipoproteins. Reduced hepatic production of apo C-III, which serves as an inhibitor of lipolysis and receptor-mediated clearance, would enhance the clearance of VLDLs. Fibrate-mediated increases in HDL-C are due to PPARα stimulation of apo A-I and apo A-II expression, which increases HDL levels. Fenofibrate is more effective than gemfibrozil at increasing HDL levels. Most fibrates have potential antithrombotic effects, including inhibition of coagulation and enhancement of fibrinolysis.

**ADME**

Fibrates are absorbed rapidly and efficiently (>90%) when given with a meal but less efficiently when taken on an empty stomach. Peak plasma concentrations are attained within 1–4 h. More than 95% of these drugs in plasma are bound to protein, nearly exclusively to albumin. The \( t_{1/2} \) of fibrates range from 1.1 (gemfibrozil) to 20 h (fenofibrate). The drugs are widely distributed throughout the body, and concentrations in liver, kidney, and intestine exceed the plasma level. Gemfibrozil is transferred across the placenta. The fibrate drugs are excreted predominantly as glucuronide conjugates (60%–90%) in the urine, with smaller amounts appearing in the feces. Excretion of these drugs is impaired in renal failure.

**Effects on Lipoprotein Levels**

Effects of fibric acid agents on lipoprotein levels differ widely, depending on the starting lipoprotein profile, the presence or absence of a genetic hyperlipoproteinemia, the associated environmental influences, and the specific fibrate used. Patients with type III hyperlipoproteinemia (dysbeta- lipoproteinemia) are among the most sensitive responders to fibrates. Elevated triglyceride and cholesterol levels are dramatically lowered, and tuberuption and palmar xanthomas may regress completely. Angina and intermittent claudication also improve.

In patients with mild hypertriglyceridermia (e.g., triglycerides < 400 mg/dL), fibrate treatment decreases triglyceride levels by up to 50% and increases HDL-C concentrations by about 15%; LDL-C levels may be unchanged or increase. Normotriglyceridemic patients with heFH usually experience little change in LDL levels with gemfibrozil, with the other fibric acid agents, reductions as great as 20% may occur in some patients. Fibrates usually are the drugs of choice for treating severe hypertriglyceridermia and the chylomicromen syndrome. While the primary therapy is to remove alcohol and lower dietary fat intake as much as possible, fibrates assist by increasing lipase clearance and decreasing hepatic triglyceride synthesis. In patients with chylomicronemia syndrome, fibrate maintenance therapy and a low-fat diet keep triglyceride levels well below 1000 mg/dL and thus prevent episodes of pancreatitis.

**Therapeutic Use**

Gemfibrozil usually is administered as a 600-mg dose taken twice daily, 30 min before the morning and evening meals. Fenofibrate is available in tablets of 48 and 145 mg or capsules containing 67, 134, and 200 mg. The choline salt of fenofibric acid is available in capsules of 135 and 45 mg. Equivalent doses of fenofibrate formulations are 135 mg of choline salt, 145-mg tablets, and 200-mg capsules. Fibrates are the drugs of choice for treating hyperlipidemic subjects with type III hyperlipoproteinemia, as well as subjects with severe hypertriglyceridermia (triglycerides > 1000 mg/dL) who are at risk for pancreatitis. A randomized clinical trial of fenofibrate added on to background statin therapy resulted in no further reduction of ASCVD risk. (ACCORD, 2010). In 2016, the FDA withdrew approval for use of fenofibrate in addition to statin therapy for ASCVD risk reduction.

**Adverse Effects and Drug Interactions**

Fibric acid compounds usually are well tolerated. GI side effects occur in up to 5% of patients. Infrequent side effects include rash, urticaria, hair loss, myalgias, fatigue, headache, impotence, and anemia. Minor increases in liver transaminases and alkaline phosphatase have been reported. Clofibrate, bezafibrate, and fenofibrate reportedly potentiate the action of warfarin. Careful monitoring of the prothrombin time and reduction in dosage of warfarin may be appropriate.

A myopathy syndrome occasionally occurs in subjects taking clofibrate, gemfibrozil, or fenofibrate and may occur in up to 5% of patients treated with a combination of gemfibrozil and higher doses of statins. Gemfibrozil inhibits hepatic uptake of statins by OATP1B1 and competes for the same glucuronosyl transferases that metabolize most statins. Thus, levels of both drugs may be elevated when they are coadministered. Patients taking this combination should be followed at 3-month intervals with careful history and determination of creatine kinase values until a stable pattern is established. Patients taking fibrates with rosuvastatin should be followed especially closely even if low doses (5–10 mg) of rosuvastatin are employed. Fenofibrate is glucuronidated by enzymes that are not involved in statin glucuronidation; thus, fenofibrate–statin combinations are less likely to cause myopathy than combination therapy with gemfibrozil and statins. All of the fibrates increase the lithogenicity of bile. Clofibrate use has been associated with increased risk of gallstone formation. Renal failure is a relative contraindication to the use of fibric acid agents, as is hepatic dysfunction. *Fibrates should not be used by children or pregnant women.*

**Inhibitor of Cholesterol Absorption**

Ezetimibe is the first compound approved for lowering total and LDL-C levels that inhibits cholesterol absorption by enterocytes in the small intestine. It lowers LDL-C levels by about 20% and may be used as adjunctive therapy with statins.

**Mechanism of Action**

Ezetimibe inhibits luminal cholesterol uptake by jejunal enterocytes, by inhibiting the transport protein NPC1L1. In human subjects, ezetimibe reduces cholesterol absorption by 54%, precipitating a compensatory increase in cholesterol synthesis that can be inhibited with a cholesterol synthesis inhibitor (e.g., a statin). The consequence of inhibiting intestinal cholesterol absorption is a reduction in the incorporation of cholesterol into chylomicrons; this diminishes the delivery of cholesterol to the liver by chylomicron remnants. The diminished remnant cholesterol content may decrease atherogenesis directly, as chylomicron remnants are very atherogenic lipoproteins. Reduced delivery of intestinal cholesterol to the liver by chylomicron remnants stimulates expression of the hepatic genes regulating LDL receptor expression and cholesterol biosynthesis. The greater expression of hepatic LDL receptors enhances LDL-C clearance from the plasma. Ezetimibe reduces LDL-C levels by 15%–20%.

**ADME**

Ezetimibe is highly water insoluble, precluding studies of its bioavailability. After ingestion, it is glucuronidated in the intestinal epithelium and absorbed and then enters an enterohepatic recirculation. Pharmacokinetic studies indicated that about 70% is excreted in the feces and about 10% in the urine (as a glucuronide conjugate). Bile acid sequestrants inhibit absorption of ezetimibe, and the two agents should not be administered together.

**Therapeutic Use**

Ezetimibe is available as a 10-mg tablet that may be taken at any time during the day, with or without food. Ezetimibe may be taken in combination with other dyslipidemia medications except bile acid sequestrants, which inhibit its absorption.

The role of ezetimibe as monotherapy of patients with elevated LDL-C levels is generally limited to the small group of statin-intolerant patients. The actions of ezetimibe are complementary to those of statins. Dual therapy with these two classes of drugs prevents both the enhanced cholesterol synthesis induced by ezetimibe and the increase in cholesterol absorption induced by statins, providing additive reductions in LDL-C levels. A combination tablet containing ezetimibe, 10 mg, and various doses of simvastatin (10, 20, 40, and 80 mg) has been approved. LDL reduction at the highest simvastatin dose plus ezetimibe is similar to that of high-intensity statins.

**Adverse Effects and Drug Interactions**

Other than rare allergic reactions, specific adverse effects have not been observed in patients taking ezetimibe. Because all statins are...
contraindicated in pregnant and nursing women, combination products containing ezetimibe and a statin should not be used by women in childbearing years in the absence of contraception.

**Omega-3 Fatty Acid Ethyl Esters**

**Mechanism of Action**

Omega-3 fatty acids, commonly EPA and DHA ethyl esters, reduce VLDL triglycerides and are used as an adjunct to diet for treatment of adult patients with severe hypertriglyceridemia. The recommended daily oral dose for patients with severe hypertriglyceridemia is 3–4 g/d administered with food.

**ADME**

The small intestine absorbs EPA and DHA, which are mainly oxidized in the liver, similar to fatty acids derived from dietary sources. The $t_{1/2}$ of elimination is approximately 50 to 80 h.

**Therapeutic Use**

Fish oil or other products containing omega-3 fatty acids are among the most common OTC herbal, vitamin, or nutritional supplements purchased by consumers each year. Doses and formulations of OTC items vary considerably. The AHA recommends that consumers eat a variety of fish at least twice a week and that fish oil supplements should only be considered for individuals with heart disease or high triglyceride levels in consultation with a medical professional. In addition to OTC fish oil products, several prescription-only products are available, generally at higher doses than those used OTC (1–1.2 g) and containing a combination of EPA and DHA. Icosapent ethyl, an ethyl ester derivative of EPA, does not contain DHA. Mixtures containing both EPA and DHA have increased LDL-C in patients with severe hypertriglyceridemia, whereas studies of EPA-only products suggest they may not significantly increase LDL-C while still reducing triglycerides. Controversy exists about when to treat hypertriglyceridemia. Modifiable secondary causes of high triglycerides such as uncontrolled diabetes and excessive alcohol intake should always be addressed prior to initiating therapy. While prescription omega-3 products generally have FDA indications for triglycerides 500 mg/dL or greater, many professional organizations advocate that such products be limited to patients with levels of 1000 mg/dL or greater who are at greatest risk for pancreatitis. The ORIGIN trial found no additional reduction in ASCVD risk associated with the use of omega-3 fatty acids versus background therapy with statins alone, calling into question the common use of fish oil supplements for “heart protection” by consumers.

**Adverse Effects and Drug Interactions**

Adverse effects may include arthralgia, nausea, fishy burps, dyspepsia, and increased LDL. Because omega-3 fatty acids may prolong bleeding time, patients taking anticoagulants should be monitored.

**PCSK9 Inhibitors**

**Mechanism of Action**

Proprotein convertase subtilisin/kexin type 9 is a pro tease that binds to the LDL receptor on the surface of hepatocytes and enhances lysosomal degradation of the LDL receptor, resulting in higher plasma LDL concentrations. Loss-of-function mutations of PCSK9 are associated with reduced LDL and lowered risk of ASCVD. Conversely, mutations leading to increased PCSK9 expression result in increased LDL levels and higher risk of ASCVD events. Two PCSK9 inhibitors, alirocumab and evolocumab, antibodies to PCSK9, are FDA-approved as adjunctive therapy to diet and maximally tolerated statin therapy in adult patients with hFH and heFH or established ASCVD requiring additional LDL lowering. Evolocumab and alirocumab are fully humanized monoclonal antibodies that bind free PCSK9, thereby interfering with its binding to the LDL receptor, leading to increased liver clearance of LDL from the circulation and lower serum LDL levels (see Figure 33–3).

Although studies are ongoing, ORION-1 describes a novel RNA interference therapeutic, inclisiran, that targets PCSK9 mRNA and thus blocks PCSK9 protein synthesis (Ray et al., 2017). Early clinical trials showed promise for an RNA interference therapeutic (ALN-PCS) that targets PCSK9 mRNA and thus blocks PCSK9 protein synthesis. Low-volume subcutaneous injections of inclisiran resulted in persistent reductions in LDL-C and other atherogenic lipids for 180 days, suggesting that a biannual subcutaneous dosing regimen might be possible.

**ADME**

The PCSK9 inhibitors are administered as subcutaneous injections either every 2 weeks or once monthly, depending on the dose and indication. Evolocumab is administered as a 140-mg injection every 2 weeks or 420 mg once monthly. For hFH, evolocumab 420 mg is administered once monthly or every 2 weeks, and alirocumab (75 mg or 150 mg) is administered once every 2 weeks. Administration requirements and storage of these medications are barriers when compared with the ease of oral dosage forms of other medications. The LDL-C plasma levels may be measured 4 to 8 weeks after initiating therapy or changing doses. These medications inhibit PCSK9 availability for 2 to 3 weeks after administration (half-life of elimination is 11 to 20 days), after which LDL levels begin to rise. Limited data are available in individuals with renal or hepatic impairment, although dose adjustments are not expected to be necessary. PCSK9 inhibitors should not be used in pregnancy because transmission across the placenta is expected. It is not known to what degree the medications will be present in breast milk, so use during lactation is not recommended.

**Therapeutic Use**

The effects of PCSK9 inhibitors are complementary to those of statins. While statins interfere with cholesterol production and stimulate the production of LDL receptors, PCSK9 inhibitors do not appear to enable more LDL receptors to be available on the surface of liver cells. PCSK9 inhibitors reduce LDL-C in a dose-dependent manner by as much as 70% when used as monotherapy or by as much as 60% in patients already on statin therapy. Indications and approvals of these agents vary between countries. Currently, PCSK9 inhibitors are not FDA-approved for treatment of dyslipidemias in statin-intolerant patients without known ASCVD, although they are being used in this population elsewhere. Among patients with known ASCVD and LDL >70 despite treatment with moderate-high intensity statins, the addition of evolocumab further reduced the risk of ASCVD events, but not death, in the FOURIER trial (Sabatine et al., 2017). Given the high cost of treatment with PCSK9 inhibitors versus relatively inexpensive statin treatment, cost-effectiveness studies will also need to be conducted in a variety of patient populations to provide further recommendations on the patients most likely to benefit from these therapies. Currently, and because of cost-effectiveness, treatment with maximally tolerated doses of statins and ezetimibe is recommended prior to initiation of PCSK9 inhibitors.

**Inhibitor of Microsomal Triglyceride Transfer**

**Lomitapide**

**Mechanism of Action**. Lomitapide mesylate is the first drug that acts by inhibiting MTP which is essential for the formation of VLDLs.

**ADME**. Lomitapide is administered with water and without food (or at least 2 h after the evening meal) because administration with food may
**Figure 33–4** LDL catabolism: effects of PCSK9, antibody to PCSK9, and statins. Hepatic LDL uptake varies with the density of LDLRs in the hepatocyte membrane. The extent of LDLR synthesis and recycling affect the availability of LDLRs, variables that PCSK9, antibody to PCSK9, and statins can influence.

**A.** In the absence of PCSK9, the LDLR is synthesized and inserted into the plasma membrane, where it binds LDL. The LDLR-LDL complex enters the hepatocyte by endocytosis. The complex dissociates within the endosome, the LDL entering the lysosomal pathway (degradation), and the LDLR being recycled to the membrane.

**B.** In the presence of PCSK9 biosynthesis, however, PCSK9 is exported into the circulation. At the surface of the hepatocyte, PCSK9 interacts with the LDLR-LDL complex, entering the endosome and preventing the dissociation of LDLRs from LDL. As a consequence, the entire LDLR-LDL-PCSK9 complex enters the lysosomal pathway for degradation. Little or no LDLR is recycled, and future LDL uptake is reduced. There are gain-of-function mutations that enhance PCSK9 activity (see text).

**C.** In the presence of PCSK9 and antibody to PCSK9, antibody to PCSK9 (AbPCSK9) prevents the binding of PCSK9 to the LDLR-LDL complex, returning the fate of the LDLR-LDL complex to that described in A, lysosomal degradation of LDL and recycling of LDLR to the membrane.

**D.** In the presence of PCSK9, antibody to PCSK9, and a statin, levels of LDLR are increased by two different mechanisms. Statins, by inhibiting HMG-CoA reductase, reduce cell cholesterol, thereby activating SREBP and upregulating transcription of genes under its control; those include genes for LDLR and PCSK9. Expression of LDLR and PCSK9 increases. The newly synthesized LDLR molecules are inserted into the plasma membrane; the newly synthesized PCSK9 is exported. In the absence of AbPCSK9, the increased extracellular PCSK9 will bind to LDLR-LDL complexes, cause their lysosomal destruction, and thereby counteract some of the statin's effect on circulating LDL and its uptake by hepatic LDLRs. In the presence of antibody to PCSK9, however, PCSK9 is complexed by AbPCSK9 and rendered inactive, permitting an increase in LDLR presence on the hepatocyte membrane and an increase in recycling of used LDLR to the membrane. Thus, by protecting LDLRs from degradation and enhancing synthesis of new LDLRs, the combination of a statin and AbPCSK9 can have a greater LDL-lowering effect than would the statin alone.
MODULATION OF PULMONARY, RENAL, AND CARDIOVASCULAR FUNCTION

Inhibitor of Apolipoprotein B-100 Synthesis

**Mipomersen**

**Mechanism of Action.** Mipomersen is the first antisense oligonucleotide inhibitor of apo B-100 synthesis. Mipomersen binds to the mRNA of apo B-100 in a sequence-specific manner, which results in degradation or disruption of the apo B-100 mRNA, thereby reducing expression of apo B-100 protein.

**ADME.** The recommended dose is 1 mL of a 200-mg/mL solution, injected subcutaneously, once a week. It is metabolized in tissues by endonucleases to form shorter oligonucleotides available for further metabolism by exonucleases. The $t_{1/2}$ is 1 to 2 months. Maximal LDL reduction occurs after 6 months of treatment. Use is contraindicated in individuals with liver disease.

**Therapeutic Use.** In 2013, mipomersen was approved by the FDA as an addition to lipid-lowering medications and diet for patients with hoFH. However, given the side-effect profile of the medication, it was not approved elsewhere, including in Europe. LDL levels are reduced 30% to 50% with this treatment, although the discontinuation rates were high in clinical trials with this drug.

**Adverse Effects and Drug Interactions.** Injection site reactions are common (80%) and include erythema, pain, itching, and hematoma. Other common adverse effects include flu-like symptoms (30%), fatigue, and headache (15%). The agent is used under an FDA risk evaluation and mitigation strategy due to concerns about hepatotoxicity. Elevations in liver enzymes greater than three times the upper limit of normal occurred in approximately 10%–15% of patients in clinical trials.

**Acknowledgement:** Thomas P. Bersot and Robert W. Mahley contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.

Introduction to Immunity and Inflammation

### Hematopoiesis

All blood cells, including immune cells, originate from pluripotent hematopoietic stem cells (HSCs) of the bone marrow. HSCs are a population of undifferentiated progenitor cells that are capable of self-renewal. On exposure to cytokines and contact with the surrounding stromal cells, HSCs can differentiate into megakaryocytes (the source of platelets), erythrocytes (red blood cells), and leukocytes (white blood cells). This process is known as hematopoiesis (Figure 34–1).

The HSC pool can be divided in two populations: long-term (LT) and short-term (ST) HSCs. LT-HSCs are capable of lifelong self-renewal, allowing for continuous hematopoiesis throughout life. ST-HSCs have limited self-renewing capability, and differentiate into multipotent progenitors—the common myeloid progenitor (CMP) and the common lymphoid progenitor (CLP). The CMP gives rise to the myeloid lineage of cells that includes megakaryocytes; erythrocytes; granulocytes (neutrophils, eosinophils, basophils, mast cells); monocytes; macrophages; and dendritic cells (DCs). In contrast, the CLP gives rise to the lymphoid lineage of cells that includes natural killer (NK) cells, B lymphocytes (B cells), and T lymphocytes (T cells) (Doulatov et al., 2012; Eaves, 2015).

### Cells of the Innate Immune System

**Granulocytes**

Granulocytes have characteristic cytoplasmic granules containing substances that, in addition to killing invading pathogens, enhance inflammation at the site of infection or injury. Neutrophils are the most abundant of the granulocytes and are generally the first cells to arrive at the site of injury. They are specialized at engulfing and killing pathogens—a process known as phagocytosis. Like neutrophils, eosinophils are also motile phagocytic cells. These cells defend against parasitic organisms such as helminths by releasing the contents of their granules, which are thought to damage the parasite membrane. Basophils and mast cells have granules that contain histamine and other pharmacologically active substances. In addition to their protective function, these cells can become dysregulated during the generation of allergic responses, in which they play an important role (see Hypersensitivity Reactions).

**Mononuclear Phagocytes**

Mononuclear phagocytes consist of monocytes and macrophages. Monocytes circulate in the blood and then migrate into tissues where they differentiate into macrophages, increase 5- to 10-fold in size, and acquire enhanced phagocytic and microbicidal activity. Macrophages engulf and eliminate pathogens, dead cells, and cellular debris. Macrophages can remain motile and travel throughout the tissues by amoeboid movements, and they can also take up residence in specific tissues, becoming tissue-resident macrophages. In addition to their role as phagocytes, macrophages release pro-inflammatory molecules, such as cytokines and eicosanoids, which are thought to damage the parasite membrane. Basophils and mast cells have granules that contain histamine and other pharmacologically active substances. In addition to their protective function, these cells can become dysregulated during the generation of allergic responses, in which they play an important role (see Hypersensitivity Reactions).

**Natural Killer Cells**

Natural killer cells are cytotoxic, granular lymphocytes that target tumor and virus-infected cells. NK cell receptors selectively target damaged or infected host cells by recognizing abnormal expression of surface molecules seen on damaged, but not healthy, cells.

**Dendritic Cells**

Dendritic cells are specialized cells that reside in tissues and stimulate adaptive immune responses. Immature DCs patrol peripheral tissues and sample their environment for infection by capturing pathogens through...
In natural reading:

**Cells of the Adaptive Immune System**

Adaptive immunity (also known as the acquired immune system) represents a branch of the immune system that is characterized by antigen specificity and immunological memory. It is mediated by B and T lymphocytes following exposure to specific antigens and is more complex than innate immunity in that it requires prior antigen processing and recognition to launch lymphocyte responses. Furthermore, in contrast to innate immune responses, which occur within hours after infection, B- and T-lymphocyte responses take days to develop.

**B Cells**

The B lymphocytes, also known as B cells, express cell surface pathogen receptors called immunoglobulins. When a naive B cell (one that has not previously encountered antigen) detects a pathogen through binding of its immunoglobulin, it begins to proliferate. Its progeny can differentiate into plasma cells or memory B cells. Plasma cells are short-lived effector cells that specialize in secreting antibodies—the soluble form of immunoglobulins. Memory B cells are long-lived and persist for years following an infection. Because memory B cells express the same immunoglobulin as their parent B cell, they mount an enhanced secondary response to a pathogen on reinfection and are the basis for B cell–mediated immunity.

**T Cells**

The T lymphocytes, also known as T cells, express cell surface pathogen receptors called TCRs. Unlike immunoglobulins, which independently recognize antigens, TCRs only recognize antigens presented on MHC molecules on the surface of DCs or other APCs. T cells are divided into two subpopulations—T helper cells (Th) and T regulatory cells (TReg). T helper cells secrete cytokines that help enhance the function of other immune cells to mediate pathogen clearance. Activated T cells can differentiate into effector cells—cells that carry out immediate functions to help clear the infection—or memory cells. Memory T cells, like memory B cells, persist for years following an infection and mount an enhanced response on reexposure to the same pathogen (see Immunological Memory).

**Organs of the Immune System**

The organs of the immune system are divided into two categories based on their function: primary lymphoid organs and secondary lymphoid organs. Lymphocyte maturation and development take place in the primary lymphoid organs, whereas secondary lymphoid organs provide sites for mature lymphocytes to interact with APCs. These lymphoid organs are interconnected by blood and lymphatic vessels.

**Primary Lymphoid Organs**

The bone marrow and thymus make up the primary lymphoid organs. Both B-cell and T-cell precursors originate in the bone marrow from HSCs. B cells complete their maturation in the bone marrow, whereas T-cell precursors migrate to the thymus to complete their development.

The bone marrow tissue is composed of a meshwork of stromal cells (e.g., endothelial cells, adipocytes, fibroblasts, osteoclasts, osteoblasts, and macrophages). Immature B cells proliferate and differentiate within the bone marrow with direct (cell–cell contact) and indirect (cytokine release) help from stromal cells. IL-1, IL-6, and IL-7 are the most important cytokines guiding the B-cell differentiation process (Hoggatt et al., 2016).

The thymus is a bilobe organ that sits above the heart. Each lobe is divided into smaller lobules that consist of an outer compartment (cortex) and an inner compartment (medulla). Both the cortex and the medulla contain a stromal cell network comprising epithelial cells, DCs, and macrophages that present self-antigens to maturing T cells. This stromal cell network is responsible for the maturation process, and the cytokines IL-1, IL-2, IL-6, and IL-7 also play an important role in this process. The thymus begins to atrophy after puberty (as the thymic stroma is eventually replaced with adipose tissue), causing a decline in T-cell output. By age 35, T-cell production drops to 20% compared to that of newborn levels, and by age 65 this number further decreases to 2% (Palmer, 2013). Importantly, once the periphery is seeded with mature T cells, the host is equipped with a diversity of naive T cells that will respond to any pathogen encounter, irrespective of diminished thymic output.

**Secondary Lymphoid Organs**

The secondary lymphoid organs, including the spleen, lymph nodes, and mucosa-associated lymphoid tissue (MALT), are the sites where adaptive immune responses are initiated. The spleen is the largest lymphoid organ, consisting of red pulp and white pulp. The red pulp is a spongy-like tissue where old or damaged erythrocytes are recycled, whereas the white pulp region consists of lymphocytes. The spleen is the only lymphoid organ that is not connected to the lymphatic vessels. Instead, immune cells enter and exit the spleen through blood vessels.
Lymph nodes are round, specialized structures that are positioned along the lymphatic vessels like beads on a chain. They collect the lymph (containing immune cells and antigens) that drains from the skin and internal organs and provide the physical location where antigen presentation and lymphocyte activation occur. The MALTs are loosely organized lymphoid tissues located in the submucosal surfaces of the gastrointestinal (GI) tract, respiratory system, and urinary tract (Neely and Flajnik, 2016).

**The Lymphatic System**

The “lymphatic system” or “lymphatics” represent a network of lymphatic vessels (similar to the circulatory system’s veins and capillaries) that are connected to lymph nodes. Similar to their circulatory counterparts, small lymph capillaries are made up of single endothelial cell layers, whereas in larger lymph vessels the endothelial cells are surrounded by layers of smooth muscle cells. Additional parts of the lymphatic system are the tonsils, adenoids, spleen, and thymus. The lymphatics collect plasma continuously leaking out from blood vessels into the interstitial spaces and return this fluid, now called lymph, to the blood (after filtration in the lymph nodes) into the subclavian veins located on either side of the neck near the clavicles. Unlike blood movement, which is driven by a pump and flows throughout the body in a continuous loop, lymph flows in only one direction—upward toward the neck—and movement originates from rhythmic contractions of the smooth muscle cells, with directionality achieved via semilunar valves inside the vessels. The lymphatics therefore have an important function in regulating both immune and fluid homeostasis.

The B and T cells, unlike other blood cells, traffic through the body via both blood and lymph (hence the term lymphocyte). After completing their development in the primary lymphoid organs, B and T cells enter the bloodstream. When lymphocytes reach blood capillaries that empty into secondary lymphoid tissues, they enter these tissues. If a naïve lymphocyte encounters antigen, it will remain in the secondary lymphoid tissue and become activated. Otherwise, if no antigen is detected, the lymphocyte then exits through the efferent lymph and reenters the bloodstream. This pattern of movement between the blood and lymph is referred to as lymphocyte recirculation, and it allows the lymphocyte population to continuously monitor the secondary lymphoid organs for signs of infection (Masopust and Schenkel, 2013; Thomas et al., 2016).

**Innate Immunity**

Innate immunity refers to the defense mechanisms that are immediately available on exposure to pathogens. These mechanisms consist of anatomical barriers, soluble mediators, and cellular responses. To establish an infection, a pathogen must first penetrate a host’s anatomical barriers, including the skin and mucous membranes. If a pathogen manages to breach these anatomical barriers, the cellular innate immune response initiates rapidly, within a matter of minutes, to activate further mechanisms of the immune response.

**Anatomical Barriers**

The skin and mucosal surfaces form the first line of defense against pathogens. The skin is made up of a thin outer layer (epidermis) of tightly packed epithelial cells and an inner layer (dermis) of connective tissue containing blood vessels, sebaceous glands, and sweat glands. The respiratory, GI, and urogenital tracts are lined by mucous membranes. Like skin, mucous membranes consist of an outer layer of epithelial cells and an underlying layer of connective tissue. These anatomical surfaces act as more than just passive barriers against pathogens. All epithelial surfaces secrete antimicrobial peptides called host defense peptides (HDPs). HDPs kill bacteria, fungi, and viruses by disrupting their membranes (Hancock et al., 2016). The sebum secreted by the sebaceous glands contains fatty acids and lactic acids that inhibit bacterial growth on the skin. Mucosal surfaces are continuously covered in mucus (a viscous fluid secreted by epithelial cells of mucous membranes) containing...
antimicrobial substances that trap foreign microorganisms and help limit the spread of infection. In the respiratory tract, this mucous is continually removed by the action of cilia on epithelial cells. In addition, all these anatomical surfaces harbor commensal microorganisms. These commensals help protect against disease by preventing colonization by harmful microorganisms. These physical, mechanical, chemical, and microbiological barriers prevent a majority of pathogens from gaining access to the cells and tissues of the body (Belkaid and Tamoutounour, 2016).

However, some pathogens manage to breach these barriers. Microbes can enter the skin through scratches, wounds, or insect bites, such as those from mosquitoes (e.g., Plasmodium falciparum, the protozoan species predominantly responsible for malaria); ticks (e.g., Borrelia burgdorferi, the bacterium responsible for Lyme disease); and fleas (e.g., Yersinia pestis, the bacterium responsible for bubonic plague). Many pathogens enter the body by penetrating mucous membranes. One example is the influenza virus, which expresses a surface molecule that allows it to attach to and invade cells in the mucous membranes of the respiratory tract.

Once a pathogen breaches these anatomical barriers, the innate immune system first responds by detecting the pathogen. This initiates an inflammatory response—mediated by soluble effectors such as complement, eicosanoids, and cytokines—that results in the recruitment of immune cells to the site of infection, direct lysis or phagocytosis of pathogens, and eventual activation of the adaptive immune response.

**Pathogen Recognition**

The first phase of an innate immune response involves pathogen detection, which is mediated by secreted and cell surface pathogen receptors. Innate immune cells recognize broad structural patterns that are conserved within microbial species but are absent from host tissues. These broad structural patterns are referred to as PAMPs and the receptors that recognize them are called PRRs. PRRs can be broadly divided into three classes: secreted, endocytic, and signaling PRRs.

**Secreted PRRs and the Complement System**

Secreted PRRs are opsonins (molecules that enhance phagocytosis) that bind to microbial cell walls and tag them for destruction by the complement system or by phagocytes. C-reactive protein and mannose-binding lectin are two examples of secreted PRRs; both are components of the acute-phase response (see Inflammation).

The plasma proteins known as the complement system are some of the first to act following pathogen entry into host tissues. Over 30 proteins make up the complement system. These proteins circulate in blood and interstitial fluid in inactive forms that become activated in sequential cascades in response to interaction with molecular components of pathogens, leading to the activation of C3, which plays the most important role in pathogen detection and clearance. Complement activation leads to the cleavage of C3 into C3b and C3a fragments. The large C3b fragment (an opsonin) attaches to pathogen surfaces in a process called complement fixation and can activate C5 and a lytic pathway that can damage the plasma membrane of adjacent cells and microorganisms. The C5a fragment attracts macrophages and neutrophils and can activate mast cells. The small C3a fragment (anaphylatoxin) also promotes inflammation. Thus, complement fixation has two functions: the formation of protein complexes that damage the pathogen’s membrane and marking the pathogen for destruction by phagocytes (Morgan and Harris, 2015).

**Endocytic PRRs**

Endocytic PRRs are expressed on the surface of phagocytic cells. These receptors mediate the uptake and transport of microbes into lysosomes, where they are degraded. The degraded microbial peptides are processed and presented to T cells by members of the MHC family of cell surface proteins. In humans, the MHC is also called human leukocyte antigen (HLA). The mannose, glucan, and scavenger receptors are part of this class of receptors.

**Signaling PRRs**

On PAMP detection, signaling PRRs trigger intracellular signaling cascades that eventually result in the production of cytokines that orchestrate the early immune response. The most-studied group of signaling PRRs are the TLRs. TLRs are a family of PRRs that recognize a variety of microbial products. These transmembrane proteins are composed of an extracellular domain that detects pathogens and a cytoplasmic signaling domain that relays information to the nucleus. TLRs are expressed on the plasma membranes and endosomes of immune cells.

Signaling through TLRs leads to activation of two distinct signal transduction pathways (see PAMPs, PRRs, and the Induction of Interferons on next page). Most TLRs signal through a pathway that promotes the activation of the transcription factor NF-κB and the production of pro-inflammatory cytokines such as IL-1, IL-6, IL-12, and TNF-α. The exception is TLR3, which signals through a pathway that leads to the activation of the transcription factor IRF3, and the production of interferon (IFN) types I and III (TLR4 is unique in that it signals through both pathways [Cao, 2016]).

Type I (IFN-α and IFN-β) and type III (IFN-λ) IFNs promote the production of ISGs in infected and neighboring cells, the products of which induce an intracellular antimicrobial program that limits the spread of infectious pathogens, particularly viruses. Type I IFNs also augment antigen presentation and cytokine production by innate immune cells, leading to enhanced adaptive immune responses (Gonzalez-Navajas et al., 2012).

**Pathogen Clearance**

Pathogens vary in the manner by which they live and replicate within their hosts. Extracellular pathogens replicate on epithelial surfaces, or within the interstitial spaces, blood, and lymph of their host. Intracellular pathogens establish infections within host cells, either in the cytoplasm or in cellular vesicles. Depending on the nature of the infection, different immune cells and effector mechanisms are involved in the control and elimination of the pathogen.

**Extracellular Pathogens**

Unlike pathogens that replicate within host cells, extracellular pathogens are accessible to soluble effector proteins. Pathogens that replicate within interstitial spaces, blood, and lymph are detected by secreted PRRs and complement proteins. Complement fixation triggers direct lysis of the pathogen and enhances pathogen uptake by phagocytic cells. The phagocytic cells involved in the clearance of extracellular pathogens are macrophages and neutrophils. Tissue-resident macrophages are long-lived cells that are present from the start of an infection. They engulf pathogens and release inflammatory mediators to alert host cells of an attack. Neutrophils, in contrast, are short-lived, circulating phagocytes. Inflammatory cues, such as those released by macrophages, recruit neutrophils to the site of infection, where they soon become the dominant phagocyte.

On entry into host tissues, the first immune cells a pathogen encounters are the tissue-resident macrophages. Macrophages phagocytize microorganisms in a nonspecific fashion through their phagocytic receptors. Proteins of the complement system enhance this process by binding to receptors expressed by macrophages. One such receptor is complement receptor 1 (CR1). CR1 molecules interact with C3b fragments that have been deposited on the pathogen’s surface, facilitating the engulfment and destruction of the pathogen.

In addition to engulfing invading pathogens, macrophages alert host cells of an infection. TLR4 engagement on macrophages leads to the production of pro-inflammatory cytokines such as IL-1, IL-6, IL-12, TNF-α, and CXCL8 (see Inflammation). These cytokines recruit immune cells, the most prominent of which are neutrophils, to the infected tissue (Lavin et al., 2015).

Circulating neutrophils have an average life span of less than 2 days. Mature neutrophils are kept in the bone marrow for up to 5 days before being released into circulation, ensuring a large reserve that can be summoned during an infection. When neutrophils sense inflammatory signals such as cytokines, chemokines, eicosanoids, ROS, or NO, they migrate to the site of infection, where they engulf and kill the invading pathogen.
In addition, neutrophils can release extracellular DNA nets that trap bacterial pathogens (von Kockritz-Blickwede and Nizet, 2009). Neutrophils die within 2 h of entry into infected tissues, forming the characteristic pus that develops at sites of infection (Kruger et al., 2015).

**Intracellular Pathogens**

The NK cells provide an early defense against intracellular pathogens. Like neutrophils, these circulating leukocytes migrate from the blood to the site of infection in response to inflammatory cues. Once at the site of infection, NK cells target and kill infected host cells.

The NK cells express receptors that deliver either activating or inhibitory signals. The ligands for the activating NK cell receptors are typically cell surface proteins whose expression is altered during infection or trauma. Healthy cells are protected from attack by NK cells because the signals generated from the inhibitory NK cell receptors dominate those generated from the activating receptors. In contrast, interaction between NK cells and infected or damaged cells shifts the balance of inhibitory and activating signals to favor an attack. This system allows NK cells to discriminate between healthy cells that should be protected and infected cells that should be destroyed.

The NK cells are stimulated by cytokines, including type I IFNs, IL-12, and TNF-α. IFN-α and IFN-β enhance NK cell cytotoxicity and induce NK cell proliferation, whereas IL-12 enhances cytokine production. The key cytokine produced by NK cells is IFN-γ, also called type II IFN. One function of IFN-γ is to activate macrophages. Activated macrophages exhibit enhanced microbialidal activity. One mechanism of their microbialidal activity is the induction of iNOS and the production of prodigious amounts of NO (Bjorkstrom et al., 2016).

**Adaptive Immunity**

Adaptive immunity refers to the arm of the immune response that changes (adapts) with each new infection. The cells responsible for adaptive immunity are B cells and T cells. The effector mechanisms used by B and T cells...
Initiation of the Adaptive Immune Response

The skin and mucosal surfaces prevent the majority of pathogens from entering host tissues and causing infections. Innate immune responses generally eliminate microorganisms that breach these barriers, typically within a few days. However, some pathogens establish an infection that cannot be controlled entirely by the innate immune response. In these cases, pathogen clearance requires the adaptive immune response.

Dendritic cells provide an essential link between innate and adaptive immunity. DCs engulf pathogens at the site of infection and travel to the lymphoid organs. Once there, they activate T cells by presenting them with fragments of the engulfed pathogen loaded on MHC molecules (see section on Antigen Processing and Presentation).

Pathogen Recognition

The innate immune system detects pathogens by a fixed repertoire of soluble and cell-surface receptors that recognize broad structures shared by different pathogens. The genes encoding these pathogen receptors are inherited from one generation to the next in a stable form.

The adaptive immune system uses a more focused strategy of pathogen recognition. B and T cells recognize pathogens by using cell surface receptors of one molecular type: BCRs and TCRs. In contrast to the stably inherited genes encoding innate immune pathogen receptors, the genes encoding BCRs and TCRs rearrange during the course of lymphocyte development. This gene rearrangement enables the development of millions of pathogen receptors with unique binding sites, each expressed by a small subset of lymphocytes. On pathogen exposure, only those lymphocytes with receptors that recognize specific components of the invading pathogen (referred to as the receptor's cognate antigen) are selected to proliferate and differentiate into effector cells.

Pathogen Receptors: BCRs and TCRs

The BCRs and TCRs are structurally related molecules. The BCR, also called immunoglobulin, is composed of two identical heavy chains and two identical light chains. Each polypeptide chain expresses an amino-terminal variable region, which contains the antigen-binding site, and a carboxy-terminal constant region. Immunoglobulins are anchored in the B-cell membrane by two transmembrane regions at the end of each heavy chain. Immunoglobulins are initially surface bound but become soluble when a B cell differentiates into a plasma cell. The soluble forms of immunoglobulins are called antibodies.

The TCR is composed of an α chain (TCRα) and a β chain (TCRβ), both anchored in the T-cell membrane by a transmembrane region. The α and β chains consist of a variable region that contains the antigen-binding site and a constant region. In contrast to immunoglobulins, TCRs remain membrane bound and are not secreted.

Both BCRs and TCRs develop through gene rearrangement. This genetic recombination process (which B cells complete in the bone marrow and T cells in the thymus) is a defining feature of the adaptive immune system. The human BCR and its soluble derivative, the antibody, are composed from genes of three loci, the IG heavy chain, the IG κ light chain, and the IG λ light chain.
**Antigen Processing and Presentation**

Immunoglobulins are capable of recognizing antigens in their native form. TCRs, in contrast, only recognize processed antigen fragments presented by specialized molecules encoded by the MHC (Figure 34–2). The MHC was first identified as a genetic complex that determines an organism’s ability to accept or reject transplanted tissue. Further studies highlighted the importance of MHC molecules in generating T1-cell and T2-cell responses. There are two types of MHC molecules involved in antigen presentation: MHC class I and MHC class II. These structurally related molecules are expressed on different cell types but perform parallel functions in priming T-cell responses.

**MHC Class I**

MHC class I molecules consist of a transmembrane glycoprotein α chain noncovalently associated with a β₂m molecule. MHC class I molecules are expressed on the surface of nearly all nucleated cells and present peptides from endogenous antigens to CD8+ Tc cells.

**MHC Class II**

MHC class II molecules consist of two noncovalently associated transmembrane glycoproteins, an α chain and a β chain. MHC class II molecules are primarily expressed on the surface of professional APCs (DCs, macrophages, B cells) and present peptides from exogenous antigens to CD4+ Tc cells.

**Antigen Processing for Presentation by MHC**

Unlike immunoglobulins, which recognize a wide range of molecular structures in their native form, TCRs can only recognize antigens in the form of a peptide bound to an MHC molecule. For a pathogen to be recognized by a T cell, pathogen-derived proteins need to be degraded into peptides—an event referred to as antigen processing (Figure 34–2). Endogenous antigens, those derived from intracellular pathogens, are processed by the cytosolic pathway for presentation by MHC class I molecules. Proteins in the cytosol are degraded into peptides by the proteasome. The resultant peptides are then transported out of the cytosol and into the ER by a protein called the TAP, which is embedded in the ER membrane. Once newly synthesized MHC class I α chains and β₂m molecules are translocated into the ER membrane, the α chains and β₂m molecules associate and bind peptide, forming a peptide-MHC complex. These peptide-MHC complexes make their way to the plasma membrane in membrane-enclosed vesicles of the Golgi apparatus.

Exogenous antigens, those derived from extracellular pathogens, are processed by the endocytic pathway for presentation by MHC class II molecules. In this pathway, extracellular pathogens are internalized by host cells through endocytosis or phagocytosis and are degraded by proteolytic enzymes within endocytic vesicles. Newly synthesized MHC class II α and β chains are translocated into the ER membrane, where they associate with a third chain, called the invariant chain. The invariant chain prevents MHC class II molecules from binding peptides in the ER and delivers MHC class II molecules to endocytic vesicles. Once in the endocytic vesicles, MHC class II molecules bind peptide and are carried to the cell surface by outgoing vesicles.

All T cells require peptide-MHC presentation by professional APCs for activation (see Primary Responses). If an intracellular pathogen does not infect a professional APC, CD8+ Tc-cell responses can be generated through a third pathway of antigen presentation called cross-presentation. Cross-presentation involves the uptake of extracellular material by professional APCs and its delivery to the MHC class I presentation pathway instead of the MHC class II presentation pathway via a mechanism that remains incompletely understood (Blum et al., 2013).

Note that protein degradation occurs continuously, even in the absence of infection. In uninfected cells, MHC molecules carry self-peptides—derived from normal cellular protein turnover—toward the cell surface. While these peptide-MHC complexes do not normally provoke an immune response, recognition of these self-peptides by autoreactive T cells can result in the development of autoimmunity (see Autoimmunity: A Breach of Tolerance).

**Lymphocyte Development and Tolerance**

Innate immune PRRs are fixed receptors that recognize broad microbial structures or structures associated with damaged host cells. These receptors rarely, if ever, recognize self-antigens expressed by healthy cells. In contrast, because BCRs and TCRs develop from gene rearrangement, receptors that recognize self-antigens expressed by healthy host cells can arise. The goal of lymphocyte development is to produce cells with functional pathogen receptors but eliminate cells whose receptors recognize self-antigens. Next, we describe the processes of B-cell and T-cell development and highlight the mechanisms that maintain self-tolerance.

**B-Cell Development**

B-cell development takes place in the bone marrow and is driven by interaction with bone marrow stromal cells and the local cytokine environment. B-cell development can be broadly divided into pre-B-, pre-B-, immature B-, and mature B-cell stages. BCR gene rearrangement starts at the early pro-B stage and continues throughout the pre-B stage. By the immature B-cell stage, B cells express fully rearranged IgM immunoglobulins on their cell surface. At this stage, immature B cells leave the bone marrow and complete their maturation in the periphery. Mature B cells express both IgM and IgD immunoglobulins on their cell surfaces (LeBien and Tedder, 2008).

Because B-cell activation depends on help from CD4+ Tc cells, negative selection of T cells whose receptors recognize self-antigens also ensures that B cells whose receptors bind to the same self-antigen will not be activated. Consequently, B cells do not undergo as rigorous of a selection process as T cells. However, B cells whose receptors recognize components of the bone marrow are negatively selected and die by apoptosis.

**T-Cell Development**

Unlike B cells, which develop in the bone marrow, T-cell precursors complete their development in the thymus. T-cell precursors enter the thymus as CD4+CD8+ DN (double negative) cells, not yet committed to the T-cell lineage. The DN T cells can be divided into four subsets—DN1 to DN4—based on the expression of certain cell surface molecules. Gene rearrangement of the TCRB chain begins during the DN2 stage and continues through the DN3 stage. After β-chain rearrangement is complete, the newly synthesized β-chain combines with a protein known as the pre-TCR, forming the pre-TCR. DN3 cells then progress to the DN4 stage and express both the CD4 and CD8 coreceptors. These cells are now referred to as CD4/CD8+ DP (double positive) cells. DP T cells proliferate rapidly, generating clones of cells expressing the same β chain. After this period of rapid proliferation, T cells begin to rearrange their α-chain genes. Because cells within each clone can rearrange a different α chain, they generate a more diverse population than if the original cell had rearranged both the β chain and a chain before proliferating. Once a DP cell expresses a fully rearranged TCR, it undergoes the processes of positive and negative selection.

The T cells migrate into the thymic cortex to undergo positive selection. The purpose of positive selection is to select for T cells whose TCRs can interact with an individual’s own MHC molecules. In the cortex, T cells interact with cortical thymic epithelial cells, which express both MHC class I and MHC class II molecules. T cells with TCRs that do not recognize self-MHC molecules die by apoptosis. T cells with TCRs that can successfully bind to self-MHC molecules are signaled to survive and proceed...
to the thymic medulla. As a result of positive selection, DP thymocytes mature into single-positive T cells that express just one coreceptor (CD4 or CD8). T cells that successfully interact with MHC class I molecules develop into CD8 T cells, whereas T cells that interact with MHC class II molecules become CD4 cells.

After positive selection, T cells migrate to the thymic medulla to undergo negative selection. The purpose of negative selection is to eliminate T cells whose TCRs recognize self-antigens. This is accomplished by medullary thymic epithelial cells, which promiscuously express self-peptides on their MHC molecules. If T cells interact with self-peptides with high affinity, they are deleted by apoptosis (Shah and Zuniga-Pflucker, 2014).

The positive and negative selection processes responsible for generating self-MHC restricted and self-tolerant T cells are rigorous. It is estimated that over 98% of thymocytes die by apoptosis within the thymus, with the majority failing at the positive selection stage. The T cells that manage to successfully complete both positive and negative selection leave the thymus and take up residence in the secondary lymphoid structures.

**Primary Responses**

The processes of lymphocyte development and gene rearrangement generate millions of unique lymphocytes that each express pathogen receptors of a single specificity. During an infection, only a small portion of these B and T cells express receptors that can recognize the invading pathogen. To increase their numbers, each lymphocyte that recognizes the invading pathogen becomes activated and proliferates, giving rise to clones expressing identical immunoglobulins or TCRs. These processes, referred to as clonal selection and clonal expansion, are essential features of lymphocyte activation and differentiation, and facilitate the effector mechanisms that B and T cells use to combat infection.

**B-Cell Activation and Antibody Production**

In the majority of primary immune responses, B-cell activation and subsequent antibody production are dependent on help from CD4 T helper (TH) cells. When circulating B cells home to secondary lymphoid tissues, they first enter at the T-cell zone. If a B cell encounters its specific antigen, cross-linking of the BCR and coreceptor induces a signal transduction cascade that mediates changes in cell surface expression of adhesion molecules and chemokine receptors, preventing the B cells from leaving the T-cell zone.

After immunoglobulins bind their cognate antigen, they internalize the antigen by receptor-mediated endocytosis and process the antigen for display by MHC class II molecules. If a CD4 TH cell recognizes its antigen, the B and T cell form a conjugate pair. This cognate interaction facilitates the delivery of T cell–derived cytokines to B cells. The most important of these cytokines is IL-4, which is essential for B-cell proliferation and differentiation into antibody-secreting plasma cells.

The initial antibodies produced by plasma cells are of generally low affinity. They help to keep the infection under control until a stronger antibody response is generated. Antibody quality improves over the course of the infection due to two processes: somatic hypermutation and isotype switching. Somatic hypermutation introduces random single-nucleotide substitutions throughout the immunoglobulin variable regions. These changes can result in immunoglobulin molecules with increased affinity for the pathogen. B cells producing these improved immunoglobulin molecules outcompete for binding to the invading pathogen and are preferentially selected to become plasma cells. As an infection proceeds, antibodies of higher affinity are produced—a process referred to as affinity maturation (Di Noia and Neuberger, 2007).

**Isotype Switching.** Immunoglobulins can be divided into five classes (isotypes) called IgA, IgD, IgG, IgM, and IgE. These isotypes differ in their heavy-chain constant regions and have specialized effector functions. IgM is the first antibody secreted following B-cell activation and marks pathogens for destruction by the complement system. As an infection proceeds, antibodies with additional effector functions are generated by isotype switching. Isotype switching is a process by which proliferating B cells rearrange their DNA to change their immunoglobulin constant regions. This process is strongly influenced by cytokines secreted by the B cell's cognate T cell (Xu et al., 2012).

**Role of Antibodies in Pathogen Clearance.** Antibodies can aid in pathogen clearance in a number of ways. They can bind to a pathogen (or toxin) and prevent it from interacting with host cells. These antibodies are called neutralizing antibodies. Antibodies can also function as opsonins—coating of pathogens with antibodies can facilitate their engulfment by phagocytic cells, which often express receptors for the constant regions of antibodies. In addition, antibody deposition can activate the complement system, leading to the direct lysis of pathogens.

**T-Cell Activation**

Naïve T cells first encounter antigen presented by DCs in the secondary lymphoid tissues. For T cells to become fully activated, they need to receive two signals (Figure 34–3):

- a primary signal generated through ligation of the TCR
- a costimulatory signal generated through ligation of a T-cell surface protein called CD28

Both of these signals must be delivered by ligands on the same APC. The primary signal is generated when the TCR engages a peptide-MHC complex. The TCR associates with an accessory molecule called CD3, forming the TCR-CD3 complex. CD3 does not influence the interaction of the TCR with its antigen but participates in the signal transduction that occurs after antigen engagement. The T-cell coreceptors CD4 and CD8 bind to the conserved regions of MHC molecules, strengthening and stabilizing the interaction between the TCR and the peptide-MHC complex. CD4 and CD8 also participate in signal transduction.

The costimulatory signal is generated when CD28 binds to its ligands, called B7-1 (CD80) and B7-2 (CD86). These costimulatory B7 molecules are only expressed on activated professional APCs, highlighting their importance in T-cell activation.

Engagement of the TCR complex activates signal transduction cascades that induce the expression of multiple genes, including NFAT, AP-1, and NF-κB. One of the most important downstream targets of these genes is IL-2, a cytokine that is essential for T-cell proliferation and survival. The IL-2 receptor, CD25, is expressed on activated T cells. When T cells become activated, they begin to express a cell surface protein called CTLA-4. This protein resembles CD28 and binds to the costimulatory B7 molecules with higher affinity than does CD28. Whereas CD28 ligation promotes T-cell activation, CTLA-4 ligation dampens T-cell activation.

This inhibitory molecule serves to keep T-cell responses in check (Brownlie and Zamoyska, 2013). In addition to CTLA-4, T cells upregulate expression of other inhibitory coreceptors such as PD1 and PSGL-1 that help to fine-tune the ensuing T-cell response (Attanasio et al., 2016; Tinoco et al., 2016).

**T-Cell Anergy.** For a naïve T cell to become fully activated, it must receive a signal through the TCR and CD28. If a T cell engages a peptide-MHC complex in the absence of a sufficient costimulatory signal, it enters a state of nonresponsiveness referred to as clonal anergy. Anergy is defined by the inability of T cells to proliferate after engaging a peptide-MHC complex due to a lack of IL-2 production and signaling (see Figure 35–2).

**CD4 T~H~1-Cell Differentiation and Effector Functions.** Following activation, naïve CD4 T cells can differentiate into specialized T~H~1-cell subsets. These T~H~1-cell subsets display unique patterns of cytokine production and perform distinct effector functions. The initial studies on T~H~1-cell differentiation generated a biphasic model in which activated T~H~1 cells differentiate into either T~H~1 cells, which defend mainly against intracellular pathogens, or T~H~2 cells, which aid in the clearance of extracellular pathogens. More recent models of T~H~1-cell differentiation have been expanded to include T~H~9, T~H~17, T~H~22, T~H~9, and T~H~9 cells (DuPage and Bluestone, 2016).

As their name implies, CD4 T~H~1 cells help activate other immune cells. T~H~1 cells secrete IFN-γ and TNF-α, which activate macrophages to kill pathogens located within their phagosomes. These cytokines also activate CD8 T cells to kill infected host cells. T~H~2 cells, which produce IL-4 and
IL-5, defend against extracellular pathogens by enhancing humoral immunity. IL-4 activates B cells to differentiate into antibody-secreting plasma cells. Th2-derived cytokines also induce class switching to IgA and IgE. Another subset of CD4 T cells, the Treg cell, is responsible for maintaining peripheral tolerance. Through various mechanisms, these cells suppress the proliferation of effector T cells, keeping the T-cell response under control.

**CD8 T-Cell Effector Functions.** The main role of CD8 T cells is to induce cytolysis of infected host cells expressing peptide-MHC class I complexes. Activated CD8 T cells kill their target cells by two distinct pathways: the granule exocytosis pathway and the Fas-FasL pathway. The granule exocytosis pathway involves the release of perforin and granule enzymes (granzymes A and B). Perforin molecules form pores in the target cell membrane, allowing the granzyme molecules to enter the cell. Uptregulation of FasL (CD95L) on activated T cells induces the aggregation of Fas (CD95) on target cells. Both of these pathways activate the caspase cascade in the target cell, resulting in programmed cell death.

In addition to their cytolytic activity, activated CD8 T cells release pro-inflammatory cytokines, including IFN-γ and TNF-α. These cytokines further aid in pathogen clearance by enhancing the activity of macrophages and neutrophils (Harty et al., 2000).

**Leukocyte Extravasation: Diapedesis**

Leukocytes fulfill most of their immunological functions outside the bloodstream in the surrounding tissues. Consequently, traversing the blood endothelial cell layer barrier is a crucial step in this process. Extravasation (diapedesis) refers to the movement of leukocytes out of the blood into the site of infection or physical tissue damage (Figure 34–4). In the case of blood monocytes, extravasation also occurs in the absence of pathophysiological events and facilitates their conversion into tissue macrophages. On a molecular level, diapedesis can be dissected into four mechanistic steps: chemotraction, rolling adhesion, tight adhesion, and transmigration (Vestweber, 2015).

While initially believed to play its most important role in innate immunity, diapedesis has garnered more attention in recent years as a pharmacological target in the treatment of chronic (inflammatory) autoimmune diseases such as multiple sclerosis or Crohn disease (see Autoimmunity). The leukocyte cell surface adhesion molecule α4β7 integrin (VLA-4) that facilitates extravasation of CD4+ T cells interacts with VCAM-1 on vascular endothelial cells. Natalizumab is a humanized monoclonal antibody directed against α4 integrin whose interference with the α4β7 integrin–VCAM-1 interaction leads to a blockade of autoreactive T-cell diapedesis into the brain and thus prevents attack on the myelin composing the nerve shielding. Similarly, natalizumab-mediated prevention of α4β7 integrin binding to the adhesion molecule MADCAM-1 found on endothelial cells of venules is responsible for the efficacy of the drug against Crohn disease. Another monoclonal antibody recently approved for the treatment of Crohn disease and ulcerative colitis is vedolizumab, which produces fewer side effects due to its α4β7-restricted binding specificity. Preventing entry of effector cells to inflammatory sites through the use of neutralizing antibodies has shown high therapeutic potential in multiple disease settings.

**Immunological Memory**

The B- and T-cell numbers decline after pathogen clearance, leaving behind a small population of memory cells. These memory cells have the ability to mount an enhanced secondary immune response on reexposure to the same pathogen. Due to their expression of certain cell surface molecules, memory T cells are more sensitive to TCR-mediated activation by peptide-MHC complexes than naive T cells. In addition, memory T cells have less-stringent requirements for costimulatory signals, allowing them to respond to...
peptide-MHC complexes displayed on cells that lack the costimulatory B7 molecules (Farber et al., 2014). Memory B cells produce better antibodies than naïve B cells because they express immunoglobulins that underwent somatic hypermutation and isotype switching during the first antigen encounter (Kurosaki et al., 2015). Combined, these properties allow for a faster and stronger secondary immune response, features that form the foundation of vaccination and subsequent "booster" or "refresher" inoculations (see Chapter 36).

**Summary: Innate and Adaptive Immunity in Infectious Diseases**

As described, the innate and adaptive immune systems work together to keep the host healthy. The innate immune response is the body's first line of defense and eliminates the majority of pathogens on its own. In the case that the innate immune system is insufficient to eliminate the pathogen, it keeps the infection in check until the adaptive immune system is able to mount a response. Pathogens will be cleared (acute infections), or they may evade the immune response and persist (chronic infections). Chronic infections such as HIV/AIDS and hepatitis B and C lead to immune system suppression that results in susceptibility to secondary infections or cancers associated with infection.

---

**Inflammation**

---

**What Is Inflammation, and What Purpose Does It Serve?**

The inflammatory response, or inflammation, is a physiologic response to tissue injury and infection, although it should be clear that inflammation is not a synonym for infection. The Romans described the characteristics of this response almost 2000 years ago: pain (dolor), heat (calor), redness (rubor), and swelling (tumor). Within minutes of tissue injury and infection, plasma proteins mediate an increase in vascular diameter (vasodilation) and vascular permeability. Vasodilation increases blood flow to the area of injury, resulting in the heating and reddening of the tissue. Increased vascular permeability allows leakage of fluid from the blood vessels into the damaged tissue, resulting in swelling (edema). Within a few hours of these vascular changes, leukocytes arrive at the site of injury. They adhere to activated endothelial cells in the inflamed region and pass through the capillary walls into the tissue (extravasation). These leukocytes phagocytize the invading pathogens and release soluble mediators—cytokines, prostaglandins, leukotrienes—that further contribute to the inflammatory response and the recruitment and activation of effector cells.

Inflammation can be acute, as in response to tissue injury, or it may be chronic, leading to progressive tissue destruction, as seen in chronic infections, autoimmunity, and certain cancers. Next, we discuss both forms of inflammation, including their triggers, the soluble mediators and cell types involved, and the resulting tissue pathology.

**Acute Inflammatory Response**

The acute inflammatory response provides protection following tissue injury and infection by restricting damage to the localized site, recruiting immune cells to eliminate the invading pathogen, and initiating the process of wound repair.

Following tissue damage, a number of plasma proteins are activated, including those of the clotting and kinin systems. The enzymatic cascade of the clotting system produces fibrin strands that accumulate to form clots, limiting the spread of infection into the blood. The enzymatic
Inflammation, Immunomodulation, and Hematopoiesis

There are pathologic conditions to which the immune system contributes, such as overreactions (allergy, autoimmunity, transplant rejection) or insufficient responses (immune deficiencies, cancer).

Hypersensitivity Reactions

The immune system mobilizes a number of effector mechanisms to eliminate pathogens from the body. These effector mechanisms typically generate a localized inflammatory response that effectively eliminates the pathogen, with minimal collateral damage to the surrounding tissue. Besides pathogens, humans come into contact with numerous foreign antigens, such as plant pollen and food. Contact with these environmental antigens does not elicit an immune response in the majority of individuals. However, in certain predisposed individuals, the immune system can mount a response to these generally innocuous antigens, resulting in tissue damage that ranges from mild irritation to life-threatening anaphylactic shock. These immune responses are referred to as allergic reactions or hypersensitivity reactions. Hypersensitivity reactions can be divided into four categories, type I to type IV, distinguished by the cell types and effector molecules involved (Burmester et al., 2003).

Type I Hypersensitivity: Immediate Hypersensitivity Reactions

Type I hypersensitivity reactions require that an individual first produces IgE antibodies on initial encounter with an antigen, also referred to as an allergen. After the antigen is cleared, the remaining antigen-specific IgE molecules will be bound by mast cells, basophils, and eosinophils that express receptors for the IgE constant region (FcεR1). This process is referred to as sensitization. On subsequent exposure to antigen, cross-linking of the IgE molecules on sensitized cells induces their immediate degranulation. The release of inflammatory mediators such as histamine, leukotrienes, and prostaglandins causes vasodilation, bronchial smooth muscle contraction, and mucus production similar to that seen during inflammatory responses to tissue injury and infection. Type I hypersensitivity reactions can be local or systemic. Systemic reactions against peanut or bee venom antigens can result in anaphylaxis, a potentially life-threatening condition.

Allergic asthma is an example of type I hypersensitivity. On exposure to certain allergens (typically inhaled), individuals with allergic asthma experience inflammation of the airways, characterized by tissue swelling and excessive mucus production. This narrowing of the airways makes it difficult to breathe (see Chapter 40).

Type II Hypersensitivity: Antibody-Mediated Cytotoxic Reactions

Type II hypersensitivities are antibody-mediated cytotoxic reactions. One example is the immunization to erythrocyte antigens during pregnancy. In an Rh-negative mother with an Rh-positive fetus (Rh inherited from the father), the mother forms antibodies against the Rh antigen when fetal blood cells come into contact with the maternal immune system, typically during delivery. If a subsequent pregnancy with an Rh-positive fetus occurs, maternal IgG antibodies can cross the placenta and cause hemolysis of fetal Rh-positive erythrocytes. Close monitoring and adequate symptomatic treatments (e.g., plasma exchange, intrauterine infusion, Rh immunoglobulin) are prescribed, as fetal symptoms can range from mild to potential fetal death from heart failure.

Type III Hypersensitivity: Immune Complex–Mediated Reactions

Type III hypersensitivity reactions are mediated by antibody-antigen complexes that form during an immune response (Figures 34–3 and 34–5). When not properly cleared, these immune complexes can settle into various tissues, where they induce complement activation. These immune complexes are of particular concern in the kidney, where they can lead to glomerulonephritis and kidney failure. While in the past
type III hypersensitivity reactions fell largely in the realm of autoimmune diseases (e.g., systemic lupus erythematosus), their incidence rate has significantly risen with the introduction of nonhuman or nonhumanized monoclonal antibodies as pharmacological agents (human antimouse antibodies). Marine or murine-human chimeric therapeutic monoclonal antibodies are “mistaken” by the patient’s immune system as potentially dangerous, foreign antigens. The resulting immune response not only “defuses” the therapeutic antibody, but also promotes the formation of antibody(mu)-antibody(hu) or antibody(chim)-antibody(hu) complexes that trigger type III hypersensitivity reactions.

**Type IV Hypersensitivity: Delayed Hypersensitivity Reactions**

Unlike type I-III hypersensitivity reactions, which are antibody mediated, type IV reactions are mediated by T cells. However, all these hypersensitivity reactions are memory responses. Haptens are molecules that are too small to function as antigens on their own. These molecules penetrate the epidermis and bind to carrier proteins in the skin. Hapten-carrier complexes are detected by APCs in the skin (Langerhans cells), which then migrate to the lymph nodes and prime T-cell responses. When an individual is reexposed to the hapten, antigen-specific T cells migrate to the skin, causing local inflammation and edema. Nickel in clothing and jewelry is a common trigger of type IV hypersensitivity reactions.

**Autoimmunity, Immune Deficiency, and Transplant Rejection**

Just as for a regular and, appropriate immune response, autoimmunity is found in either humoral (autoantibody) or cellular (T-cell) responses. As described in the section on lymphocyte development, the process of central tolerance limits the development of autoreactive B and T cells. This process is imperfect, and mechanisms of peripheral tolerance are in place to limit the activity of self-reactive lymphocytes that manage to escape thymic deletion. Peripheral tolerance is primarily mediated by two mechanisms: the action of T<sub>reg</sub> cells (see section on CD4<sup>+</sup> T<sub>reg</sub> cell effector functions), and the induction of T-cell anergy. Naïve T cells require costimulatory signals to become activated. Consequently, autoreactive T cells typically will not become activated if they interact with an MHC molecule expressing self-antigen because most tissues do not express costimulatory molecules. Induction of anergy leaves T cells unresponsive, even on subsequent exposure to antigen with sufficient costimulation.

**Autoimmunity: A Breach of Tolerance**

Several theories exist that aim to explain the origins of individual autoimmune disorders:

- **Molecular Mimicry.** The hypothesis of “molecular mimicry” reasons that unique pathogen-derived antigens resemble endogenous host antigens. If an infection occurs, the immune system’s defensive arsenal (antibodies, CTLs, and NK cells) not only attack the pathogen-derived antigen but also assault the host’s structurally similar antigen, thus causing autoimmunity in the form of “collateral damage.”

- **Relationship Between Autoimmunity and the HLA System.** Individuals with specific HLA types are more likely to develop certain autoimmune diseases (e.g., type I diabetes, ankylosing spondylitis, celiac disease, systemic lupus erythematosus). A reasonable explanation for this observation might be found in the fact that particular HLA proteins are more “efficient” than others in presenting antigens and consequently might erroneously activate T cells.

- **Altered Thymic Function.** Thymic T-cell selection is crucial to central tolerance, and type I IFNs, which are highly induced during infectious events, also govern several steps in T-cell selection. Therefore, pathogen-induced disturbances to thymic events might negatively affect elimination of autoreactive T cells. Regardless of the mechanism, central tolerance has thus far not been exploited for pharmacological intervention.

**Immune Deficiencies**

Primary immunodeficiency encompasses genetic or developmental defects in the immune system that leave the individual susceptible to infections to various degrees. Severe forms (severe combined immunodeficiency) are typically diagnosed in early childhood and are associated with significantly reduced life expectancy. Presently, nine classes of primary immunodeficiency are recognized, totaling over 120 unique conditions. Unfortunately, current treatment options are limited to supportive therapy in the form of antiviral, antifungal, and antibacterial drugs.
Acquired immunodeficiency refers to the loss of immune function due to environmental exposure. These conditions encompass patients receiving immune-suppressive therapy for autoimmune disorders or to prevent transplant rejections. Acquired immunodeficiency is also commonly observed in patients suffering from hematopoietic malignancies, as tumor cells outcompete functional leukocytes for space in the bone marrow or blood. Probably the most common use for the term, however, is in connection with HIV infection, the underlying cause for AIDS (see Chapter 35).

Transplant Rejection

"Host-versus-graft disease" or "graft-versus-host disease" results from the immunological rejection of a transplanted tissue by the recipient's immune system, or in cases where bone marrow is transplanted, the "new" immune system might attack the host's tissues. The intensity of rejection is minimized with increased compatibility between donor and recipient; however, a lifelong regimen of immunosuppressive drugs is unavoidable (see Chapter 64).

Classical immunosuppressive therapy employs glucocorticoids (e.g., prednisone), inhibitors of T-cell activation (e.g., cyclosporine), T-cell proliferation inhibitors (e.g., mycophenolic acid) or mTOR inhibitors (e.g., sirolimus) that inhibit production of IL-2, a cytokine essential for T-cell activation and proliferation. Treatment of transplant rejection also has benefited from advances in monoclonal antibody therapy, and antibodies directed against the IL-2 receptor (e.g., daclizumab) or CD20 (e.g., rituximab) are now available to prevent transplant rejection (Figure 35–2).

Cancer Immunotherapy

As described previously, T-cell responses are modulated by a balance between costimulatory signals, exemplified by CD28 ligation, and coinhibitory signals, such as those provided by CTLA-4 or PD1 ligation. Immune checkpoints refer to inhibitory (often negative-feedback) pathways that limit the amplitude and duration of an immune response. Under normal physiological conditions, immune checkpoints protect tissues from damage during an immune response and contribute to the maintenance of self-tolerance. In conditions of chronic viral infections and cancers, chronic antigen persistence results in the development of dysfunctional "exhausted" T cells. Exhausted T cells are actively suppressed by inhibitory signals that limit their effector functions and turn off their target cell-killing capacity. These inhibitory pathways resulting in T-cell exhaustion have been documented in mice, monkeys, and humans, highlighting their importance in modulating T-cell function.

Cancer cells express a variety of genetic and epigenetic alterations that distinguish them from their normal counterparts. These tumor-associated antigens can be recognized by the host immune system; antitumor T cells are generated, which then eliminate these transformed cells. However, tumors frequently develop immune resistance mechanisms that evade the host’s immune attack. One of these evasion strategies involves the manipulation of immune-inhibitory pathways or immune checkpoints. Tumors avoid being destroyed by actively stimulating these inhibitory receptors to turn off antitumor T cells. Figure 34–7 provides an overview of activating and inhibitory coreceptors and the drugs (monoclonal antibodies) that target them. In general, these antibodies work by releasing the brake on
antitumor T cells and reinvigorating them to kill tumors. It is important to be aware that whereas some monoclonal antibodies block their respective target (PD1), others block the respective ligand (PD-L1). The therapeutic goal is to interfere with this inhibitory interaction that is actively suppressing T cells in the tumor microenvironment.

The two immune checkpoint receptors that have been the most extensively characterized in the context of cancer immunotherapy are CTLA-4 and PD1. These inhibitory molecules are highly expressed on antitumor T cells. When bound by their respective ligands (CD80/86 and PD-L1/PD-L2) on APCs or tumor cells, these inhibitory receptors dampen the T-cell response, albeit by different intracellular pathways. As antitumor T cells express PD1, tumor cells engage it through their expression of PD-L1. The tumor effectively inactivates the T cells and the tumor continues to grow (Pardoll, 2012; Tang et al., 2016). These pathways are further discussed in the cancer therapy chapters (Chapters 65–68).

Immunotherapy to cancers holds great promise for treating patients with advanced disease, as evidenced by the success of clinical trials using this technology. Biologics to stimulate antitumor T cells have been rapidly approved by the FDA and have become the first line of treatment of cancers such as metastatic melanoma, non–small cell lung cancer, and renal cell carcinoma. In addition, anti-PD1, anti–PD-L1, and anti–CTLA-4 therapies are currently in clinical trials to assess their efficacy in head and neck cancers, breast cancer, small cell lung cancer, Hodgkin lymphoma, gastric cancer, hepatocellular carcinoma, bladder cancer, ovarian cancer, colon cancer, and Merkel cell carcinoma. It is important to note that only a small fraction of patients respond to checkpoint monotherapy, and this frequency can increase when patients are given combination therapy, such as administering both anti-PD1 and anti–CTLA-4 antibodies. Furthermore, combination strategies that include checkpoint blockade paired with radiation or chemotherapy may further increase responsiveness in cancer patients.

One consequence of checkpoint blockade is that autoreactive T cells are also unleashed after therapy. Patients can develop toxicities that include hepatic, pneumonitis, colitis, rash, vitiligo, and endocrine pathology. Greater immunotherapy efficacy will likely be achieved when drugs are developed to target other inhibitory pathways and are used in combination, but caution must be evaluated to ensure patient safety (Callahan et al., 2016).

In addition to solid tumors, liquid tumors like CLL are also being targeted by immunotherapeutic approaches. Patient T cells are engineered to express chimeric antigen receptors (CARs) comprising antibody-binding domains connected to domains that activate T cells. In the case of CLL, CAR T cells recognize CD19 on B cells, and their chimeric receptor sustains T activation. CAR T cells are engineered from patient blood, expanded in vitro; then, millions are infused into the same patient. These cells then circulate in the patient and recognize all B cells expressing CD19 and destroy them. This cellular therapy has shown promise in patients with CLL with high durable objective responses (Kalos et al., 2011).

IMMUNOTHERAPY FOR MULTIPLE SCLEROSIS
- Clinical Features and Pathology

This chapter reviews the components of the immune response and drugs that modulate immunity via immunosuppression or tolerance. Four major classes of immunosuppressive drugs are discussed: glucocorticoids (see Chapter 46), calcineurin inhibitors, antiproliferative and antimetabolic agents (see Chapter 66), and antibodies. While there are similarities, the approach to the use of immunosuppressants in transplant rejection has evolved separately from the approaches used to treat autoimmune disease and thus is presented separately. Finally, the chapter ends with a brief case study of immunotherapy for the autoimmune disease MS.

The Immune Response

The immune system evolved to discriminate self from nonself. Innate immunity (natural immunity) is primitive, does not require priming, and is of relatively low affinity, but it is broadly reactive. Adaptive immunity (learned immunity) is antigen specific, depends on antigen exposure or priming, and can be of very high affinity. The two arms of immunity work closely together, with the innate immune system most active early in an immune response and adaptive immunity becoming progressively dominant over time.

The major effectors of innate immunity are complement, granulocytes, monocytes/macrophages, NK cells, mast cells, and basophils. The major effectors of adaptive immunity are B and T lymphocytes. B lymphocytes make antibodies; T lymphocytes function as helper, cytolytic, and regulatory (suppressor) cells. These cells not only are important in the normal immune response to infection and tumors but also mediate transplant rejection and autoimmunity.

Immunoglobulins (antibodies) on the B-lymphocyte surface are receptors for a large variety of specific structural conformations. In contrast, T lymphocytes recognize antigens as peptide fragments in the context of self MHC antigens (called HLAs in humans) on the surface of APCs, such as dendritic cells, macrophages, and other cell types expressing MHC class I and class II antigens. Once activated by specific antigen recognition, both B and T lymphocytes are triggered to differentiate and divide, leading to release of soluble mediators (cytokines, lymphokines) that perform as effectors and regulators of the immune response. Chapter 34 presents a more detailed view of the immune system at the levels of the molecules, cells, and organs involved in immunity.

Immunosuppression

Immunosuppressive drugs are used to dampen the immune response in organ transplantation and autoimmune disease. In transplantation, the major classes of immunosuppressive drugs used today are the following:
- Glucocorticoids
- Calcineurin inhibitors
- Antiproliferative/antimetabolic agents
- Biologicals (antibodies)

Table 35–1 summarizes the sites of action of representative immunosuppressants on T-cell activation. These drugs are successful in treating conditions such as acute immune rejection of organ transplants and autoimmune diseases. However, such therapies often require lifelong use and nonspecifically suppress the entire immune system, exposing patients in some instances to higher risks of infection and cancer. The calcineurin inhibitors and daily glucocorticoids, in particular, are nephrotoxic and diabetogenic, respectively, thus restricting their usefulness in a variety of clinical settings.

Monoclonal and polyclonal antibody preparations directed at both T cells and B cells or against cytokines such as TNF-α are important therapies providing an opportunity to more specifically target immune pathways. Finally, newer small molecules and antibodies have expanded the arsenal of immunosuppressives. In particular, mTOR inhibitors (sirolimus, everolimus, temsirolimus) (Budde et al., 2011; Euvrard et al., 2012), and anti-CD25 (IL-2R) antibodies (basiliximab, daclizumab) (Nashan, 2005) target growth factor pathways. Belatacept (Satyananda and Shapiro, 2014) inhibits T-cell costimulation. Thus, there are useful pharmacological tools that can substantially limit clonal expansion and potentially promote tolerance (Goldfarb-Rumyantsev et al., 2006; Krensky et al., 1990).

General Approach to Organ Transplantation Therapy

Organ transplantation therapy is organized around five general principles.
1. Carefully prepare the patient and select the best available ABO blood type–compatible HLA match for organ donation.
2. Employ multitier immunosuppressive therapy; simultaneously use several agents, each of which is directed at a different molecular target within the allograft response. Synergistic effects permit use of the
Employ intensive induction and lower-dose maintenance drug protocols; greater immunosuppression is required to gain early engraftment or to treat established rejection than to maintain long-term immunosuppression. The early high risk of acute rejection is replaced over time by the increased risk of the medications’ side effects, necessitating a slow reduction of maintenance immunosuppressive drugs.

3. Employ intensive induction and lower-dose maintenance drug protocols; greater immunosuppression is required to gain early engraftment or to treat established rejection than to maintain long-term immunosuppression. The early high risk of acute rejection is replaced over time by the increased risk of the medications’ side effects, necessitating a slow reduction of maintenance immunosuppressive drugs.

4. Investigation of each episode of transplant dysfunction is required, including evaluation for recurrence of the disease, rejection, drug toxicity, and infection (keeping in mind that these various problems can and often do coexist).

5. Reduce dosage or withdraw a drug if its toxicity exceeds its benefit (Danovitch et al., 2007).

### Biological Induction Therapy

In many transplant centers, induction therapy with biological agents is used to delay the use of the nephrotoxic calcineurin inhibitors or to intensify the initial immunosuppressive therapy in patients at high risk of rejection (i.e., repeat transplants, broadly presensitized patients, African American patients, or pediatric patients). This strategy has been an important component of immunosuppression since the 1960s, when Starzl and colleagues demonstrated the beneficial effect of antilymphocyte globulin (ALG) in the prophylaxis of rejection. Two preparations are FDA-approved for use in transplantation: lymphocyte immune globulin (Atgam) and antithymocyte globulin (ATG; Thymoglobulin) (Brennan et al., 2006; Nashan, 2005). ATG is the most frequently used depleting agent. Alemtuzumab, a humanized anti-CD52 mAb that produces prolonged lymphocyte depletion, is approved for use in CLL and MS but is increasingly used off label as induction therapy in transplantation (Jones and Coles, 2014).

Most limitations of murine-based mAbs generally were overcome by the introduction of chimeric or humanized mAbs that lack antigenicity and have a prolonged serum t½. Antibodies derived from transgenic mice carrying human antibody genes are labeled “humanized” (90%–95% human) or “fully human” (100% human); antibodies derived from human cells are labeled “human.” However, all three types of antibodies are of equal efficacy and safety. Chimeric antibodies generally contain about 33% mouse protein and 67% human protein and can still produce an antibody response that results in reduced efficacy and shorter t½ compared to humanized antibodies.

Biological agents for induction therapy in the prophylaxis of rejection currently are used in about 70% of de novo transplant patients. Biological agents for induction can be divided into two groups: the depleting agents and the immune modulators. The depleting agents consist of lymphocyte immune globulin, ATG, and muromonab-CD3 mAb; their efficacy derives from their ability to deplete the recipient’s CD3-positive cells at the time of transplantation and antigen presentation. The second group of biological agents, the anti–IL-2R mAbs, do not deplete T lymphocytes, but rather block IL-2–mediated T-cell activation by binding to the α chain of IL-2R (CD25). For patients with high levels of anti-HLA antibodies and humoral rejection, more aggressive therapies include plasmapheresis, intravenous immunoglobulin, and rituximab, a chimeric anti-CD20 mAb (Brennan et al., 2006; Chan et al., 2011; Guerra et al., 2011; Nashan, 2005; Sureshkumar et al., 2012).

### Abbreviations

- **ALG:** antilymphocyte globulin
- **APC:** antigen-presenting cell
- **ATG:** antithymocyte globulin
- **AUC:** area under the curve
- **CD:** cluster of differentiation
- **CLL:** chronic lymphocytic leukemia
- **CNS:** central nervous system
- **CTL:** cytotoxic T lymphocyte
- **CTLA4:** cytotoxic T-lymphocyte–associated antigen 4
- **FKBP-12:** FK506-binding protein 12
- **CYP:** cytochrome P450
- **GVHD:** graft-versus-host disease
- **HLA:** human leukocyte antigen
- **HRPT:** hypoxanthine–guanine phosphoribosyl transferase
- **IFN-β:** interferon beta
- **IL-2R:** interleukin 2 receptor
- **IL-1 receptor antagonist:** IL-1Ra
- **IL-1:** interleukin
- **IL-2:** interleukin
- **IL-6:** interleukin
- **IL-10:** interleukin
- **IL-12:** interleukin
- **IL-17:** interleukin
- **IL-21:** interleukin
- **IL-23:** interleukin
- **IL-24:** interleukin
- **IL-25:** interleukin
- **IL-26:** interleukin
- **IL-27:** interleukin
- **IL-28:** interleukin
- **IL-29:** interleukin
- **IL-30:** interleukin
- **IL-31:** interleukin
- **IL-32:** interleukin
- **IL-33:** interleukin
- **IL-34:** interleukin
- **IL-35:** interleukin
- **IL-36:** interleukin
- **IL-37:** interleukin
- **IL-38:** interleukin
- **IL-39:** interleukin
- **IL-40:** interleukin
- **IL-41:** interleukin
- **IL-42:** interleukin
- **IL-43:** interleukin
- **IL-44:** interleukin
- **IL-45:** interleukin

Maintenance Immunosuppression

Basic immunosuppressive therapy uses multiple drugs simultaneously, typically a calcineurin inhibitor, glucocorticoids, and mycophenolate (a purine metabolism inhibitor), each directed at a discrete step in T-cell activation (Vincenti et al., 2008). Glucocorticoids, azathioprine, cyclosporine, tacrolimus, mycophenolate, sirolimus, belatacept, and various mAbs and polyclonal antibodies all are approved for use in transplantation.

Therapy for Established Rejection

Low doses of prednisone, calcineurin inhibitors, purine metabolism inhibitors, sirolimus, or belatacept are effective in preventing acute cellular rejection; they are less effective in blocking activated T lymphocytes and thus are not very effective against established, acute rejection or for the total prevention of chronic rejection. Therefore, treatment of established rejection requires the use of agents directed against activated T cells. These include glucocorticoids in high doses (pulse therapy), polyclonal antilymphocyte antibodies, or muromonab-CD3 (licensed by the FDA but not currently marketed in the U.S. due to decreased use).

Glucocorticoids

The introduction of glucocorticoids as immunosuppressive drugs in the 1960s played a key role in making organ transplantation possible. Prednisone, prednisolone, and other glucocorticoids are used alone and in combination with other immunosuppressive agents for treatment of transplant rejection and autoimmune disorders. The pharmacological properties of glucocorticoids are described in Chapter 46.

Mechanism of Action

Glucocorticoids have broad anti-inflammatory effects on multiple components of cellular immunity, but relatively little effect on humoral immunity. Glucocorticoids bind to receptors inside cells and regulate the transcription of numerous other genes (see Chapter 46). Glucocorticoids also curtail activation of NF-κB, suppress formation of pro-inflammatory cytokines such as IL-1 and IL-6, inhibit T cells from making IL-2 and proliferating, and inhibit the activation of CTLs. In addition, glucocorticoid-treated neutrophils and monocytes display poor chemotaxis and decreased lysosomal enzyme release.

Therapeutic Uses

There are numerous therapeutic indications for glucocorticoids. They commonly are combined with other immunosuppressive agents to prevent and treat transplant rejection. Glucocorticoids also are efficacious for treatment of GVHD in bone marrow transplantation. Glucocorticoids are routinely used to treat autoimmune disorders such as rheumatoid arthritis, systemic lupus erythematosus, systemic dermatomyositis, psoriasis and other skin conditions, asthma and other allergic disorders, inflammatory bowel disease, inflammatory ophthalmic diseases, autoimmune hematological disorders, and acute exacerbations of MS (see multiple sclerosis section). Lower-dose oral glucocorticoids, however, appear to have different biologic effects; low-dose oral prednisone made optic neuritis worse compared to high-dose intravenous solumedrol (Beck et al., 1992). In addition, glucocorticoids limit allergic reactions that occur with other immunosuppressive agents and are used in transplant recipients to block first-dose cytokine storm caused by treatment with muromonab-CD3 and to a lesser extent ATG (see Antithymocyte Globulin). Most transplant centers use an initial high dose of intravenous solumedrol with tapering to a maintenance dose of 5–10 mg/d in the long term. Currently, more than one-third of kidney transplant centers in the U.S. aim to withdraw steroids within the first 3 months after transplantation (Bergmann et al., 2012).

Toxicity

Extensive glucocorticoid use often results in disabling and life-threatening adverse effects. These effects include growth retardation in children, avascular necrosis of bone, osteopenia, increased risk of infection, poor wound healing, cataracts, hyperglycemia, and hypertension (see Chapter 46). The advent of combined glucocorticoid/calcineurin inhibitor regimens has allowed reduced doses or rapid withdrawal of steroids, resulting in lower steroid-induced morbidities (Vincenti et al., 2008).

Calcineurin Inhibitors

The most effective immunosuppressive drugs in routine use are the calcineurin inhibitors cyclosporine and tacrolimus (Figure 35–1), which target intracellular signaling pathways induced as a consequence of TCR activation (Figure 35–2). Cyclosporine and tacrolimus bind to an immunophilin (cyclophilin for cyclosporine or FKBP-12 for tacrolimus), resulting in subsequent interaction with calcineurin to block its phosphatase activity. Calcineurin-catalyzed dephosphorylation is required for movement of a component of the NFAT into the nucleus. NFAT, in turn, is required to induce a number of cytokine genes, including IL-2, a prototypic T-cell growth and differentiation factor (Verghe et al., 2014).

Tacrolimus

Tacrolimus is a macrolide antibiotic produced by Streptomyces tsukubaensis. Because of perceived slightly greater efficacy and ease of blood level monitoring, tacrolimus has become the preferred calcineurin inhibitor in most transplant centers (Ekberg et al., 2007).

Mechanism of Action. Like cyclosporine, tacrolimus inhibits T-cell activation by inhibiting calcineurin. Tacrolimus binds to an intracellular protein, FKBP-12, an immunophilin structurally related to cyclophilin. A complex of tacrolimus–FKBP-12, Ca2+, calmodulin, and calcineurin then forms, and calcineurin phosphatase activity is inhibited (see Figure 35–2). Inhibition of phosphatase activity prevents dephosphorylation and nuclear translocation of NFAT and inhibits T-cell activation. Thus, although the intracellular receptors differ, cyclosporine and tacrolimus target the same pathway for immunosuppression.

ADME. Tacrolimus is available for oral administration as capsules and extended-release capsules (0.5, 1, and 5 mg); extended-release tablets (0.75, 1, and 4 mg); and a solution for injection (5 mg/mL). Sublingual tacrolimus has been used off label for the short term in patients who are unable to receive medications orally. Because of intersubject variability in pharmacokinetics, individualized dosing is required for optimal therapy. For tacrolimus, whole blood is the preferred sampling compartment; the trough drug level in whole blood seems to correlate better with clinical events for tacrolimus than for cyclosporine. Target concentrations are 10–15 ng/mL in the early preoperative period and 6–8 ng/mL at 3 months posttransplantation. Gastrointestinal absorption is incomplete and variable. Target concentrations are dependent on sampling technique and on product-release characteristics, immediate- versus extended-release forms. Food decreases the rate and extent of absorption. Plasma protein binding of tacrolimus is 75%–99%, involving primarily albumin and α1-acid glycoprotein. The t1/2 of tacrolimus is about 12 h. Tacrolimus is extensively metabolized in the liver by CYP3A; some of the metabolites are active. The bulk of excretion of the parent drug and metabolites is in the feces.

Therapeutic Uses. Tacrolimus is indicated for the prophylaxis of solid-organ allograft rejection in a manner similar to cyclosporine (see Cyclosporine) and is used off label as rescue therapy in patients with rejection episodes despite “therapeutic” levels of cyclosporine. Recommended initial oral doses are 0.2 mg/kg/d for adult kidney transplant patients, 0.1–0.15 mg/kg/d for adult liver transplant patients, 0.075 mg/kg/d for adult heart transplant patients, and 0.15–0.2 mg/kg/d for pediatric liver transplant patients in two divided doses 12 h apart. These dosages are intended to achieve typical blood trough levels in the 5–20 ng/mL range (Goring et al., 2014). Note that the oral dose of tacrolimus depends on product release characteristics (immediate- vs. extended-release formulation) and the specific cocktail of medications selected for prophylaxis.

Toxicity. Nephrotoxicity; neurotoxicity (e.g., tremor, headache, motor disturbances, seizures); GI complaints; hypertension; hyperkalemia; hyperglycemia; and diabetes are all associated with tacrolimus use. Tacrolimus has a negative effect on pancreatic islet β cells, and glucose intolerance and diabetes mellitus are well-recognized complications of
tacrolimus-based immunosuppression. While combined use of calcineurin inhibitors and glucocorticoids is particularly diabetogenic, new-onset diabetes after transplantation (NODAT) incidence was significantly higher with tacrolimus compared to cyclosporine, the other calcineurin inhibitor. Obese patients, African American or Hispanic transplant recipients, or those with a family history of type 2 diabetes or obesity are especially at risk. As with other immunosuppressive agents, there is an increased risk of secondary tumors and opportunistic infections. Notably, tacrolimus does not adversely affect uric acid or LDL cholesterol. Diarrhea and alopecia are common in patients on concomitant mycophenolate therapy.

**Drug Interactions.** Because of its potential for nephrotoxicity, tacrolimus blood levels and renal function should be monitored closely. Coadministration with cyclosporine results in additive or synergistic nephrotoxicity; therefore, a delay of at least 24 h is required when switching a patient from cyclosporine to tacrolimus. Because tacrolimus is metabolized mainly by CYP3A, the potential interactions described in the following section for cyclosporine also apply for tacrolimus. Per the label, concomitant use of tacrolimus with cyclosporine or sirolimus is not recommended for prophylaxis against renal transplant rejection.

**Cyclosporine**

Cyclosporine (cyclosporin A) is a cyclic polypeptide of 11 amino acids, produced by the fungus *Beauveria nivea*, that inhibits calcineurin activity (Azzi et al., 2013).

**Mechanism of Action.** Cyclosporine forms a complex with cyclophilin, a cytoplasmic-receptor protein present in target cells (Figure 35–2). This complex binds to calcineurin, inhibiting Ca²⁺-stimulated dephosphorylation of the cytosolic component of NFAT. When cytoplasmic NFAT is dephosphorylated, it translocates to the nucleus and complexes with nuclear components required for complete T-cell activation, including transactivation of IL-2 and other lymphokine genes. Calcineurin phosphatase activity is inhibited after physical interaction with the cyclosporine/cyclophilin complex.

At the level of immune system function, cyclosporine suppresses some humoral immunity but is more effective against T-cell–dependent immune mechanisms such as those underlying transplant rejection and some forms of autoimmunity. It preferentially inhibits antigen-triggered signal transduction in T lymphocytes, blunting expression of many lymphokines, including IL-2, and the expression of antiapoptotic proteins.
Cyclosporine also increases expression of TGF-β, a potent inhibitor of IL-2–stimulated T-cell proliferation and generation of CTLs (Colombo and Ammirati, 2011; Molnar et al., 2015).

ADME. Because cyclosporine is lipophilic and highly hydrophobic, it is formulated for clinical administration using castor oil or other strategies to ensure solubilization. Cyclosporine can be administered intravenously or orally. The intravenous preparation is provided as a solution in an ethanol–polyoxyethylated castor oil vehicle that must be further diluted in 0.9% sodium chloride solution or 5% dextrose solution before injection. The oral dosage forms include soft gelatin capsules and oral solutions. Cyclosporine supplied in the original soft gelatin capsule is absorbed slowly, with 20%–50% bioavailability. A modified microemulsion formulation, Neoral, has become the most widely used preparation. It has more uniform and slightly increased bioavailability compared to the original formulation. It is provided as 25- and 100-mg soft gelatin capsules and a 100-mg/mL oral solution. The original and microemulsion formulations are not bioequivalent and cannot be used interchangeably without heightened monitoring of drug concentrations and assessment of graft function. A second modified formulation, Gengraf, is also marketed, and like Neoral, is not interchangeable with nonmodified cyclosporine formulations. Transplant units need to educate patients that the cyclosporine preparation known as Sandimmune and its generics are not the same as Neoral and its generics, such that one preparation cannot be substituted for another without risk of inadequate immunosuppression or increased toxicity. The danger of unauthorized, inadvertent, unmonitored, or inappropriate substitution of nonequivalent formulations can result in graft loss and other adverse patient outcomes.

Blood levels taken 2 h after a dose administration (so-called C2 levels) may correlate better with the AUC than other single points, but no single time point can simulate the exposure better than more frequent drug

Figure 35–2 T-cell activation and sites of action of immunosuppressive agents. The TCR recognizes antigens bound to the MHC. A costimulatory signal is required for T-cell activation: The CD80/CD86-CD28 interaction from the APC to the T cell. Activation leads to IL-2 production (in a positive-feedback loop) and a host of other events, some of which are bracketed in the lower right-hand corner. Numerous agents are available to suppress T-cell activation. Cyclosporine and tacrolimus bind to immunophilins (cyclophilin and FKBP, respectively), forming a complex that inhibits the phosphatase calcineurin and the calcineurin-catalyzed dephosphorylation that permits translocation of NFAT into the nucleus. NFAT is required for transcription of IL-2 and other growth and differentiation–associated cytokines (lymphokines). Sirolimus (rapamycin) works downstream of the IL-2R, binding to FKBP; the FKBP-sirolimus complex binds to and inhibits the mTOR, a kinase involved in cell cycle progression (proliferation). MMF and azathioprine inhibit nucleic acid synthesis, thereby inhibiting T-cell proliferation. The antibody muromunab (OKT3) inhibits TCR function via interaction with its CD3 component. Daclizumab and basiliximab block IL-2 signaling by interacting with the alpha subunit of the IL-2R complex (CD25). Several antibodies can block the systemic effects of released TNF. Alemtuzumab, by binding to CD52, marks the cell for destruction, thereby depleting CD52+ cells.
Cyclosporine absorption is incomplete following oral administration and varies with the individual patient and the formulation used. Cyclosporine is distributed extensively outside the vascular compartment. After intravenous dosing, the steady-state volume of distribution reportedly is as high as 3–5 L/kg in solid-organ transplant recipients. The elimination of cyclosporine from the blood generally is biphasic, with a terminal t1/2 of 5–18 h. After intravenous infusion, clearance is about 5–7 mL/min/kg in adult recipients of renal transplants, but results differ by age and between different patient populations. For example, clearance is slower in cardiac transplant patients and more rapid in children. Thus, the intersubject variability is so large that individual monitoring is required.

After oral administration of cyclosporine (as Neoral), the time to peak blood concentrations is 1.5–2 h. Administration with food delays and decreases absorption. High- and low-fat meals consumed within 30 min of administration decrease the AUC by about 13% and the maximum concentration by 33%. This makes it imperative to individualize dosage regimens for outpatients. Cyclosporine is extensively metabolized in the liver by hepatic CYP3A and to a lesser degree in the GI tract and kidneys. At least 25 metabolites have been identified in human bile, feces, blood, and urine. All of the metabolites have reduced biological activity and toxicity compared to the parent drug. Cyclosporine and its metabolites are excreted principally through the bile into the feces, with about 6% excreted in the urine. Cyclosporine also is excreted in human milk. In the presence of hepatic dysfunction, dosage adjustments are required. No adjustments generally are necessary for patients on dialysis or with renal failure.

**Therapeutic Uses.** Clinical indications for cyclosporine are kidney, liver, heart, and other organ transplantation; rheumatoid arthritis; psoriasis; and xerophthalmia. Its use in dermatology is discussed in Chapter 70. Cyclosporine usually is combined with other agents, especially glucocorticoids and either azathioprine or mycophenolate, and, most recently, sirolimus. The dose of cyclosporine varies, depending on the organ transplanted and the other drugs used in the specific treatment protocol(s). The initial dose generally is not given before the transplant because of the concern about nephrotoxicity. For renal transplant patients, therapeutic algorithms have been developed to delay cyclosporine or tacrolimus introduction until a threshold renal function has been attained. Dosing is guided by signs of rejection (too low a dose), renal or other toxicity (too high a dose), and close monitoring of blood levels. Great care must be taken to differentiate renal toxicity from rejection in kidney transplant patients. Ultrasound-guided allograft biopsy is the best way to assess the basis for renal dysfunction. Because adverse reactions have been ascribed more frequently to the intravenous formulation, this route of administration is discontinued as soon as the patient can take the drug orally.

In rheumatoid arthritis, cyclosporine is used in severe cases that have not responded to methotrexate. Cyclosporine can be combined with methotrexate, but the levels of both drugs must be monitored closely. In psoriasis, cyclosporine is indicated for treatment of adult immunocompetent patients with severe and disabling disease for whom other systemic therapies are contraindicated or have failed. Because of its mechanism of action, there is a theoretical basis for the use of cyclosporine in a variety of other T-cell–mediated diseases. Cyclosporine reportedly is effective in Behçet’s, acute ocular syndrome, endogenous uveitis, atopic dermatitis, inflammatory bowel disease, and nephrotic syndrome, even when standard therapies have failed.

**Toxicity.** The principal adverse reactions to cyclosporine therapy are renal dysfunction and hypertension; tremor, hirsutism, hyperlipidemia, and gum hyperplasia also are frequently encountered. Hypertension occurs in about 50% of renal transplant and almost all cardiac transplant patients. Hyperuricemia may lead to worsening of gout, increased P-glycoprotein activity, and hypercholesterolemia (see Chapters 5, 33, and 38). Nephrotoxicity occurs in the majority of patients and is the major reason for cessation or modification of therapy. Combined use of calcineurin inhibitors and glucocorticoids is particularly diabetogenic, although this seems more problematic in patients treated with tacrolimus (see previous Tacrolimus section). Cyclosporine, as opposed to tacrolimus, is more likely to produce elevations in LDL cholesterol.

**Drug Interactions.** Cyclosporine interacts with a wide variety of commonly used drugs, and close attention must be paid to drug interactions. Any drug that affects CYP3A, especially CYP3A4, may affect cyclosporine blood concentrations. Substances that inhibit this enzyme can decrease cyclosporine metabolism and increase blood concentrations. These include CYP3A channel blockers (e.g., verapamil, nicardipine); antifungal agents (e.g., fluconazole, ketoconazole); antibiotics (e.g., erythromycin); glucocorticoids (e.g., methylprednisolone); HIV-protease inhibitors (e.g., indinavir); and other drugs (e.g., allopurinol, metoclopramide). Grapefruit juice inhibits CYP3A and the P-glycoprotein multidrug efflux pump and thereby can increase cyclosporine blood concentrations. In contrast, drugs that induce CYP3A activity can increase cyclosporine metabolism and decrease blood concentrations. Such drugs include antibiotics (e.g., nafcillin, rifampin); anticonvulsants (e.g., phenobarbital, phenytoin); and others (e.g., octreotide, ticlopidine).

Interactions between cyclosporine and sirolimus require that administration of the two drugs be separated by time. Sirolimus aggravates cyclosporine-induced renal dysfunction, while cyclosporine increases sirolimus-induced hyperlipidemia and myelosuppression. Additive nephrotoxicity may occur when cyclosporine is coadministered with NSAIDs and other drugs that cause renal dysfunction; elevation of methotrexate levels may occur when the two drugs are coadministered, as can reduced clearance of other drugs, including prednisolone, digoxin, and statins (Azzi et al., 2013; Ekberg et al., 2007).

**Antiproliferative and Antimetabolic Drugs**

**Sirolimus**

Sirolimus (rapamycin) is a macrocyclic lactone produced by Streptomyces hygroscopicus.

**Mechanism of Action.** Sirolimus inhibits T-lymphocyte activation and proliferation downstream of the IL-2 and other T-cell growth factor receptors (see Figure 35–2). Like cyclosporine and tacrolimus, therapeutic action of sirolimus requires formation of a complex with an immunophilin, in this case FKBP-12. The sirolimus–FKBP-12 complex does not affect calcineurin activity; rather, it binds to and inhibits the protein kinase mTOR, which is a key enzyme in cell cycle progression. Inhibition of mTOR blocks cell cycle progression at the G1 → S phase transition.

In animal models, sirolimus not only inhibits transplant rejection, GVHD, and a variety of autoimmune diseases, but also has effects for several months after discontinuation, suggesting a tolerizing effect (see Tolerance). A newer indication for sirolimus is the avoidance of calcineurin inhibitors, even when patients are stable, to protect kidney function (Schena et al., 2009).

**ADME.** After oral administration, sirolimus is absorbed rapidly and reaches a peak blood concentration within about 1 h after a single dose in healthy subjects and within about 2 h after multiple oral doses in renal transplant patients. Systemic availability is about 15%, and blood concentrations are proportional to dose between 3 and 12 mg/m2. A high-fat meal decreases peak blood concentration by 34%; sirolimus therefore should be taken consistently either with or without food, and blood levels should be monitored closely. About 40% of sirolimus in plasma is protein bound, especially to albumin. The drug partitions into formed elements of blood (blood-to-plasma ratio = 38 in renal transplant patients). Sirolimus is extensively metabolized by CYP3A4 and is transported by P-glycoprotein. The bulk of total excretion is via the feces. Although some of its metabolites are active, sirolimus itself is the major active component in whole blood and contributes more than 90% of the immunosuppressive effect. The blood t1/2 after multiple doses in stable renal transplant patients is 62 h. A loading dose of three times the maintenance dose will provide nearly steady-state concentrations within 1 day in most patients.
**Therapeutic Uses.** Sirolimus is indicated for prophylaxis of organ transplant rejection, usually in combination with a reduced dose of calcineurin inhibitor and glucocorticoids. Sirolimus has been used with glucocorticoids and mycophenolate to avoid permanent renal damage. Sirolimus dosing regimens are relatively complex, with blood levels generally targeted between 5 and 15 ng/mL. It is recommended that the daily maintenance dose be reduced by approximately one-third in patients with hepatic impairment. Sirolimus also has been incorporated into stents to inhibit local cell proliferation and blood vessel occlusion (Moes et al., 2015).

**Toxicity.** The use of sirolimus in renal transplant patients is associated with a dose-dependent increase in serum cholesterol and triglycerides that may require treatment. Although immunotherapy with sirolimus per se is not considered nephrotoxic, patients treated with cyclosporine plus sirolimus have impaired renal function compared to patients treated with cyclosporine alone. Sirolimus can worsen proteinuria and should be used with caution in patients with GFR below 30% or proteinuria; these conditions can worsen renal failure. Renal function and proteinuria therefore must be monitored closely in such patients. Lymphocele, a known surgical complication associated with renal transplantation, is increased in a dose-dependent fashion by sirolimus, requiring close postoperative follow-up.

Other adverse effects include anemia, leukopenia, thrombocytopenia, mouth ulcer, hypokalemia, and GI effects. Delayed wound healing may occur with sirolimus use. This mTOR inhibitor has been shown to have an antinecrotic effect, especially on skin cancer; it is considered the immunosuppressant of choice in patients with a history of malignancy. Temsirolimus is specifically approved for kidney (but not skin) cancer, while everolimus is approved for a variety of cancers (but not skin cancer). As with other immunosuppressive agents, there is an increased risk of infections.

**Drug Interactions.** Because sirolimus is a substrate for CYP3A4 and is transported by P-glycoprotein, close attention to interactions with other drugs that are metabolized or transported by these proteins is required (see Chapters 5 and 6). Dose adjustment may be required when sirolimus is coadministered with CYP3A4 and P-glycoprotein inhibitors (such as diltiazem) or strong inducers (such as rifampin) (Alberú et al., 2011; Euvrard et al., 2012).

**Everolimus**

Everolimus [40-O-(2-hydroxyethyl)-rapamycin] is FDA-approved for treatment of astrocytoma, breast cancer, kidney and liver transplant rejection prophylaxis, pancreatic neuroendocrine tumor, renal angiomyolipoma, and renal cell cancer. It is chemically closely related to sirolimus but has distinct pharmacokinetics. The main difference is a shorter t₁/₂ and thus a shorter time to achieve steady-state concentrations of the drug. Doseage on a milligram per kilogram basis is similar to (but not the same as) that of sirolimus. In kidney transplant rejection prophylaxis, the initial dose of everolimus is 0.75 mg twice daily, with later adjustment based on serum concentrations. As with sirolimus, the combination of a calcineurin inhibitor and an mTOR inhibitor produces worse renal function at 1 year than does calcineurin inhibitor therapy alone, suggesting a drug interaction between the mTOR inhibitors and the calcineurin inhibitors that reduces rejection but enhances toxicity. The toxicity of everolimus and the potential for drug interactions seem to be the same as with sirolimus (Budde et al., 2011; Moes et al., 2015). Like sirolimus, individualization of drug dose through therapeutic drug monitoring is required.

**Azathioprine**

Azathioprine is a purine antimetabolite. It is an imidazolyl derivative of 6-mercaptopurine, metabolites of which can inhibit purine synthesis.

**Mechanism of Action.** Following exposure to nucleophiles such as glutathione, azathioprine is cleaved to 6-MP, which in turn is converted to additional metabolites that inhibit de novo purine synthesis (see Chapter 66). A fraudulent nucleotide, 6-thio-IMP, is converted to 6-thio-GMP and finally to 6-thio-GTP, which is incorporated into DNA. Cell proliferation thereby is inhibited, impairing a variety of lymphocyte functions. Azathioprine appears to be a more potent immunosuppressive agent than 6-MP (Hardinger et al., 2013).

**ADME.** Azathioprine is well absorbed orally and reaches maximum blood levels within 1–2 h after administration. The t₁/₂ of azathioprine is about 10 min, and the t₁/₂ of 6-MP is about 1 h. Other metabolites have a t₁/₂ of up to 5 h. Blood levels have limited predictive value because of extensive metabolism, significant activity of many different metabolites, and high tissue levels attained. Azathioprine and mercaptopurine are moderately bound to plasma proteins and are partially dialyzable. Both are rapidly removed from the blood by oxidation or methylation in the liver or erythrocytes. Renal clearance has little impact on the biological effectiveness or toxicity.

**Therapeutic Uses.** Azathioprine is indicated as an adjunct for prevention of organ transplant rejection and in severe rheumatoid arthritis. The usual starting dose of azathioprine is 3–5 mg/kg/d. Lower initial doses (1 mg/kg/d) are used in treating rheumatoid arthritis. Complete blood count and liver function tests should be monitored.

**Toxicity.** The major side effect of azathioprine is bone marrow suppression, including leukopenia (common), thrombocytopenia (less common), or anemia (uncommon). Other important adverse effects include increased susceptibility to infections (especially varicella and herpes simplex viruses), hepatotoxicity, alopecia, GI toxicity, pancreatitis, and increased risk of neoplasia.

**Drug Interactions.** Xanthine oxidase, an enzyme of major importance in the catabolism of azathioprine metabolites, is blocked by allopurinol. Hence, the combination of azathioprine with allopurinol should be avoided. Adverse effects resulting from coadministration of azathioprine with other myelosuppressive agents or angiotensin-converting enzyme inhibitors include leukopenia, thrombocytopenia, and anemia as a result of myelosuppression.

**Mycophenolate Mofetil**

Mycophenolate mofetil is the 2-morpholinoethyl ester of MPA (Darji et al., 2008; Molnar et al., 2015).

**Mechanism of Action.** Mycophenolate mofetil is a prodrug that is rapidly hydrolyzed to the active drug MPA, a selective, noncompetitive, reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), an enzyme in the de novo pathway of guanine nucleotide synthesis. B and T lymphocytes are highly dependent on this pathway for cell proliferation; MPA thus selectively inhibits lymphocyte proliferation and functions, including antibody formation, cellular adhesion, and migration.

**ADME.** Mycophenolate mofetil undergoes rapid and complete metabolism to MPA after oral or intravenous administration. MPA is then metabolized to the inactive glucuronide MPAG. The parent drug is cleared from the blood within a few minutes. The t₁/₂ of MPA is ~16 h. Most (87%) is excreted in the urine as MPAG. Plasma concentrations of MPA and MPAG are increased in patients with renal insufficiency.

**Therapeutic Uses.** Mycophenolate mofetil is indicated for prophylaxis of transplant rejection, and it is typically used in combination with glucocorticoids and a calcineurin inhibitor but not with azathioprine. Combined treatment with sirolimus is possible, although potential drug interactions necessitate careful monitoring of drug levels. The approved dose for liver transplantation rejection prophylaxis is 1 g twice daily. For renal transplant plants, 1 g is administered orally or intravenously (over 2 h) twice daily (2 g/d). A higher dose, 1.5 g twice daily (3 g/d), may be recommended for African American renal transplant patients and all liver and cardiac transplant patients. MMF is increasingly used off label in systemic lupus. MMF has been used to treat a number of different inflammatory disorders, including MS and sarcoidosis. A delayed-release formulation of MPA is available; it does not release MPA under acidic conditions (pH < 5), as in the stomach, but is soluble in neutral pH, as in the intestine. The enteric coating results in a delay in the time to reach maximum MPA concentrations (Darji et al., 2008).

**Toxicity.** The principal toxicities of MMF are GI and hematologic: leukopenia, pure red cell aplasia, diarrhea, and vomiting. The MPA formulation has been introduced to reduce the frequent GI upset and has had variable results. There also is an increased incidence of some infections, especially sepsis associated with cytomegalovirus. Tacrolimus in combination with...
Polyclonal antisera are generated by repeated injections of human thymocytes (ATG) or lymphocytes (ALG) into animals and then purifying the serum immunoglobulin fraction. These preparations vary in efficacy and toxicity from batch to batch.

The capacity to produce mAbs (Figure 35–3) has overcome the problems of variability in efficacy and toxicity seen with the polyclonal products, but mAbs are more limited in their target specificity. The first-generation murine mAbs have been replaced by newer humanized or fully human mAbs that lack antigenicity, have a prolonged $t_{1/2}$, and can be mutagenized to alter their affinity to Fc receptors.

Another class of biological agents being developed for both autoimmunity and transplantation are fusion receptor proteins. These agents consist of the ligand-binding domains of receptors bound to the Fc region of an immunoglobulin (usually IgG1) to provide a longer $t_{1/2}$ (Baldo, 2015). Examples of such agents include abatacept (CTLA4-Ig) and belatacept (a second-generation CTLA4-Ig), discussed in the Costimulatory Blockade section.

**Antithymocyte Globulin**

Antithymocyte globulin is a purified gamma globulin from the serum of rabbits immunized with human thymocytes (Thiyagarajan et al., 2013). It is provided as a sterile, freeze-dried product for intravenous administration after reconstitution with sterile water. ATG is one of many immune globulin preparations used therapeutically, generally for passive immunization (see Table 35–2 and Chapter 36).

**Mechanism of Action.** Antithymocyte globulin contains cytotoxic antibodies that bind to CD2, CD3, CD4, CD8, CD11a, CD18, CD25, CD44, CD45, and HLA class I and II molecules on the surface of human T lymphocytes. The antibodies deplete circulating lymphocytes by direct cytotoxicity (both complement and cell mediated) and block lymphocyte function by binding to cell surface molecules involved in the regulation of cell function.

**Therapeutic Uses.** Antithymocyte globulin is used for induction immunosuppression, although the approved indications are for the treatment and prophylaxis of acute renal transplant rejection in combination with other immunosuppressive agents and for the treatment of aplastic anemia. Antilymphocyte-depleting agents (Thymoglobulin, Atgam, and OKT3) are not registered for use as induction immunosuppression. A course of antithymocyte-globulin often is given to renal transplant patients with delayed graft function to avoid early treatment with the nephrotoxic calcineurin inhibitors, thereby aiding in recovery from ischemic reperfusion injury. The recommended dose of Thymoglobulin for acute rejection of renal grafts is 1.5 mg/kg/d (over 4–6 h) for 7–14 days. Mean T-cell counts fall by day 2 of therapy. The recommended dose of Atgam for acute rejection of renal grafts is 10–15 mg/kg/d for 14 days. ATG also is used for acute rejection of other types of organ transplants and for prophylaxis of rejection.

**Toxicity.** Polyclonal antibodies are xenogeneic proteins that can elicit major side effects, including fever and chills with the potential for hypotension. Premedication with corticosteroids, acetaminophen, or an antihistamine and administration of the antiserum by slow infusion (over 4–6 h) into a large-diameter vessel minimize such reactions. Serum sickness and glomerulonephritis can occur; anaphylaxis is rare. Hematologic complications include leukopenia and thrombocytopenia. As with other immunosuppressive agents, there is an increased risk of infection and malignancy, especially when multiple immunosuppressive agents are combined. No drug interactions have been described; anti-ATG antibodies develop but do not limit repeated use.

**Monoclonal Antibodies**

Immunotherapy and the Nature of Costimulation and Inhibition

Multiple costimulatory and inhibitory molecules interact to regulate T-cell responses. Immune activation requires two signals that emanate from the interaction of membrane proteins on APCs and T cells.
INFLAMMATION, IMMUNOMODULATION, AND HEMATOPOIESIS

A growing number of antibodies directed at these interacting proteins permits interruption of immune activation to produce a state of immune suppression. Figures 35–2 and 35–4 point out some of these antibodies, which are especially useful in preventing rejection after organ transplantation, as summarized in the material that follows.

In what might be considered an antiparallel system to activation, inhibitory regulation of T-cell activity can also result from the interaction of paired membrane ligands of APCs and T cells (Figure 35–4C). These points of negative regulation are called immune checkpoints. By targeting and blocking these immune checkpoints, antibodies can permit T-cell activation to proceed, unfettered by downregulation (Figure 35–4C and 35–4D). Activating immune attacks of tumor cells by blockade of immune checkpoints is producing new therapeutic options for cancer therapy (Calilah et al., 2016; Topalian et al., 2015). Chapter 67 presents the use of immunotherapy in cancer treatment.

**Anti-CD3 Monoclonal Antibodies**

CD3 is a component of the TCR complex on the surface of human T lymphocytes (Figure 35–2). Antibodies directed at the ε chain of CD3 have been used with considerable efficacy in human transplantation. The anti-CD3 antibody is monoclonal and targets the CD3 chain of the TCR, inducing its endocytosis and T-cell inactivation and removal through phagocytosis. The original mouse IgG2a antihuman CD3 mAb, muromonab-CD3 (OKT3), is no longer marketed due to its side effects: It frequently causes cytokine release syndrome and severe pulmonary edema. Nevertheless, muromonab remains FDA-registered and could be reintroduced to the market at any time.

Recently, genetically altered anti-CD3 mAbs have been developed that are "humanized" to minimize the occurrence of antiantibody responses and mutated to prevent binding to Fc receptors. In initial clinical trials, a humanized anti-CD3 mAb that does not bind to Fc receptors reversed acute renal allograft rejection without causing the first-dose...
cytokine release syndrome. Humanized anti-CD3 mAbs are also in phase 3 trials in patients with type 1 autoimmune diabetes.

**Anti-CD52 Monoclonal Antibody (Alemtuzumab)**

*Alemtuzumab* is a depleting humanized anti-CD52 mAb.

**Mechanism of Action.** Alemtuzumab binds the CD52 protein that is wildly expressed on B cells and T-cells, as well as macrophages, NK cells, and some granulocytes. Alemtuzumab binding to CD52 induces an antibody-dependent lysis of cells and a profound leukopenia that may last for more than a year (Jones and Coles, 2014).

**Therapeutic Uses.** Alemtuzumab is used mainly for induction of immunosuppressive therapy and allows the avoidance of the early high dose of steroids. For transplants, the most common regimen is a single intraoperative dose of 30 mg. Alemtuzumab is also used for the treatment of refractory acute cellular- and antibody-mediated rejections with the same dose used during induction. The drug is licensed for the management of CLL and MS (CAMMS223 Investigators et al., 2008).

**Toxicity.** Neutropenia remains the most common adverse effect seen with alemtuzumab. Almost half of the patients will also experience thrombocytopenia and anemia. Another major side effect is autoimmune hemolytic anemia and other autoimmune diseases thought to be due to immune reconstitution after the profound lymphocyte depletion.

**Anti-IL-2 Receptor (Anti-CD25) Antibodies**

Daclizumab is a humanized murine complementarity-determining region/human IgG1 chimeric mAb. Basiliximab is a murine-human chimeric mAb. Both are licensed for use in conjunction with cyclosporine.

---

**Figure 35–4 T-cell activation: costimulation and coinhibitory checkpoints.** Numerous membrane CD proteins may be expressed on the APC and the T cell that lead to signaling interactions between ligands and receptors. These interactions can enhance or reduce the activation state of the T cell. Two signals are required for T-cell activation: presentation of an antigen ligand to the TCR and signaling by an additional “costimulatory” pair. A. The primary signal, **signal 1**, is the interaction of the TCR with the MHC-antigen complex on the APC. Activation requires a second, costimulatory interaction. B. **Signal 2**, the costimulatory interaction between CD28 on the T cell (the costimulatory receptor) and the costimulatory ligand on the APC, CD80/CD86, leads to T-cell activation. Additional costimulatory signals, such as the interaction of CD154 with CD40 on the APC, can further enhance T-cell activation (+). In the absence of costimulation, a T cell can become anergic or unresponsive. C. Additional APC–T-cell interactions can occur after T-cell activation, and some can be inhibitory, providing **immune checkpoints** that are important for reducing autoimmunity and for regulating the size and extent of immune responses. For example, the interaction of CD152 (CTLA4) with CD80/86 produces inhibitory signals that attenuate T-cell activation and proliferation (–). CD28 and CD152 compete for binding to CD80/CD86. As the figure suggests, the affinity of CD152 for CD80/CD86 exceeds that of CD28, and the equilibrium lies toward the formation of the inhibitory signaling complex, CD152–CD80/CD86. T cells may express varying amounts of another important modifier, PD1 (CD279). When liganded by PD-1, PD1 produces inhibitory signals (↑ protein phosphatase activity, ↓ signaling by TCR, ↓ MAPK activity; see Figure 35–2) and reduces T-cell proliferation, leading to T-cell exhaustion, a state of hyporesponsiveness. When PD1 is highly expressed, as during conditions of chronic viral infection and cancer, suppression of T-cell activity via this pathway can be very effective; this pathway can facilitate continued viral replication and tumor progression. D. These immune checkpoints are useful sites for pharmacological regulation of T-cell activation. For instance, the agents abatacept and belatacept are fusion proteins that contain the CTLA4 domain of CD154 and act as decoys. These agents block costimulation of T cells by binding CD80/CD86 (see additional examples in Figure 35–2). Nivolumab and pembrolizumab are antibodies to PD1 and block interaction of PD1 with PD-L1, thereby blocking the immune suppression that would normally ensue and producing a state of immune hyperactivity. Checkpoint inhibitors that enhance immune responses are being used in cancer therapy (see Chapter 67). Antibodies can also be designed to be stimulatory ligands at checkpoints, to aid in generating a state of immune suppression that would be useful in treating autoimmune diseases.
Mechanism of Action. The anti-CD25 mAbs bind with high affinity to the α subunit of the IL-2 receptor (Figure 35–2) and act as a receptor antagonist, inhibiting T-cell activation and proliferation without inducing cell lysis (Table 35–1). Daclizumab has a somewhat lower affinity but a longer t₁/2 (20 days) than basiliximab (Brennan et al., 2006). In addition, the induction of CD56+ CD4+ T cells is associated with response to therapy in patients with MS (D’Amico et al., 2015).

Therapeutic Uses. Anti-CD25 mAbs are used for induction therapy in solid-organ transplantation. They are also in phase 3 clinical trials in patients with MS. The long t₁/2 of daclizumab (20 days) results in saturation of the IL-2Ra on circulating lymphocytes for up to 120 days after transplantation. Daclizumab is administered in five doses (1 mg/kg given intravenously over 15 min in 50–100 mL of normal saline) starting immediately preoperatively and subsequently at biweekly intervals.

The t₁/2 of basiliximab is 7 days. In trials, basiliximab was administered in a fixed dose of 20 mg preoperatively and on days 0 and 4 after transplantation. This regimen of basiliximab saturated IL-2Ra on circulating lymphocytes for 25–35 days after transplantation. Basiliximab was used with a maintenance regimen consisting of cyclosporine and prednisone and was found to be safe and effective when used in a maintenance regimen consisting of cyclosporine, MMF, and prednisone.

While daclizumab and basiliximab are comparable in effectiveness, daclizumab has a more costly dosing regimen. The higher cost has reduced demand, and daclizumab is now produced only for use in treating MS.

Toxicity. Basiliximab and daclizumab seem to be relatively safe as induction agents, with most of the clinical trials reporting adverse reactions rates comparable to placebo. No cytokine-release syndrome has been noted, but anaphylactic reactions and rare lymphoproliferative disorders and opportunistic infections may occur. No drug interactions have been described.

Belatacept, a Fusion Protein
Belatacept is a fusion protein composed of a modified Fc fragment of a human immunoglobulin linked to the extracellular domain of the CTLA4 (CD152) that is present on T cells (Figure 35–5). This second-generation CTLA4-Ig has two amino acid substitutions, increasing its affinity for CD80 (2-fold) and CD86 (4-fold), yielding a 10-fold increase in potency in vitro compared to CTLA4-Ig (Chinen et al., 2015).

Mechanism of Action. Induction of specific immune responses by T lymphocytes requires two signals: an antigen-specific signal via the TCR and a costimulatory signal provided by the interaction of molecules such as CD28 on CD4 lymphocytes with CD80 and CD86 on APCs and CD2 engagement by LFA-3 (CD58) on CD8 cells (Figure 35–4) (Riella and Sayegh, 2013). Belatacept is a selective T-cell costimulation blocker that potently binds the cell surface costimulatory ligands (CD80 and CD86) present on APCs, interrupting their interaction with CD28 on T cells (signal 2). The inhibition of signal 2 inhibits T-cell activation, promoting anergy and apoptosis.

Disposition and Pharmacokinetics. Belatacept is the first intravenous maintenance therapy in solid-organ transplantation. Belatacept’s pharmacokinetics were determined to be linear, with zero-order intravenous infusion and first-order elimination within the standard dose range of 5–10 mg/kg. The t₁/2 of belatacept is about 11 days.

Therapeutic Uses. Preclinical renal transplant studies showed that belatacept did not induce tolerance but did prolong graft survival. Belatacept is FDA approved as an alternative to calcineurin inhibitors as a strategy to prevent long-term calcineurin inhibitor toxicity (Satyananda and Shapira, 2014; Talawila and Pengel, 2015). Belatacept has been approved specifically for prophylaxis of organ rejection in adult patients receiving a kidney transplant in combination with basiliximab induction, MMF, and corticosteroids.

The BENEFIT trial compared two belatacept-based regimens to cyclosporine and showed better kidney function and metabolic profile with belatacept-treated patients compared to cyclosporine. Patients were induced with basiliximab and maintained on MMF and a prednisone taper. While infusions of belatacept are required relatively frequently early after transplantation, it becomes once/month by the end of the first or third month, depending on the dosage regimen chosen (Masson et al., 2014).

Toxicity. An increased risk of posttransplant lymphoproliferative disorder in Epstein-Barr virus seronegative patients has been observed with belatacept treatment. Hence, its use is restricted to Epstein-Barr virus seropositive patients. Infusion-related reactions occur infrequently, and the drug is generally well tolerated (Masson et al., 2014).

Drug Interactions. No specific pharmacokinetic drug-drug interactions have been reported with belatacept (Pestana et al., 2012).

General Approach to Treatment of Autoimmune Diseases
Genome-wide association scans have clearly clustered genetic variants around a group of diseases that appear to be mediated by autoimmune responses (Farh et al., 2015). Therapeutically, these diseases respond well to immunosuppression and the use of mAbs directed against cytokine pathways. However, these genetic investigations have revealed that a risk variant in one disease may be protective in another (Maier et al., 2009), consistent with the observation that inhibiting cytokine responses in one disease state, such as anti–TNF-α in rheumatoid arthritis, may lead to flare-ups in another disease (MS).

Anti–IL-2 Receptor (Anti–CD25) Antibodies
Anti–IL-2R mAbs discussed previously have been FDA-approved as a second line drug for patients with MS.

Anti–CD52
Matute lymphocytes express CD52 (CAMPATH-1 antigen), a negatively charged membrane dodecapeptide. Alemtuzumab, discussed previously, is a humanized mAb that binds to CD52 and targets the lymphocyte for destruction. In addition to the uses mentioned, alemtuzumab is approved for use in CLL and MS.
Anti-TNF Reagents

Tumor necrosis factor alpha is a pro-inflammatory cytokine that has been implicated in the pathogenesis of several immune-mediated intestinal, skin, and joint diseases. Several diseases (rheumatoid arthritis, Crohn disease) are associated with elevated levels of TNF-α. As a result, a number of anti-TNF agents have been developed as treatments.

**Infliximab** is a chimeric IgG1 mAb containing a human constant (Fc) region and a murine variable region. It binds with high affinity to TNF-α and prevents the cytokine from binding to its receptors. Infliximab is approved in the U.S. for treating the symptoms of rheumatoid arthritis and is typically used in combination with methotrexate in patients who do not respond to methotrexate alone. Infliximab also is approved for treatment of symptoms of moderate-to-severe ulcerative colitis in patients who have failed to respond to conventional therapy (see Chapter 51). Other FDA-approved indications include ankylosing spondylitis, plaque psoriasis, psoriatic arthritis, and ulcerative colitis. About 1 in 6 patients receiving infliximab experiences an infusion reaction characterized by fever, urticaria, hypotension, and dyspnea within 1–2 h after antibody administration. The development of antinuclear antibodies, and rarely a lupus-like syndrome, has been reported in association with infliximab (Meroni et al., 2015).

**Etanercept** is a fusion protein that targets TNF-α. Etanercept contains the ligand-binding portion of a human TNF receptor fused to the Fc portion of human IgG1 and binds to TNF-α and prevents it from interacting with its receptors. It is approved for treatment of the symptoms of rheumatoid arthritis, ankylosing spondylitis, plaque psoriasis, polyarticular juvenile idiopathic arthritis, and psoriatic arthritis. Etanercept can be used in combination with methotrexate in patients who have not responded adequately to methotrexate alone. Injection-site reactions (i.e., erythema, itching, pain, or swelling) have occurred in more than one-third of etanercept-treated patients.

**Adalimumab** is another anti-TNF product for intravenous use. This recombinant human IgG1 mAb is approved for use in rheumatoid arthritis, ankylosing spondylitis, Crohn disease, juvenile idiopathic arthritis, plaque psoriasis, psoriatic arthritis, and ulcerative colitis.

**Golimumab** is a human IgG1 (anti-TNF-α) monoclonal antibody. Golimumab alone or in combination with methotrexate is approved for treatment of moderately to severely active rheumatoid arthritis and active psoriatic arthritis. It is also approved for treatment of patients with ankylosing spondylitis and moderately to severely active ulcerative colitis. Golimumab is administered by subcutaneous injections and is available in 50- and 100-mg doses.

**Certolizumab pegol** is a humanized pegylated antibody specific to TNF-α. Pegylation of the Fab’ fragment provides sustained activity. This agent is approved for the treatment of adults with Crohn disease and rheumatoid arthritis, active psoriatic arthritis, and active ankylosing spondylitis. It is available as 200 mg lyophilized powder or 200-mg/mL prefilled sterile injections for subcutaneous administration.

**Toxicity.** All anti-TNF agents (i.e., infliximab, etanercept, adalimumab, golimumab, certolizumab) increase the risk of serious infections, lymphomas, and other malignancies. For example, fatal hepatosplenic T-cell lymphomas have been reported in adolescent and young adult patients with Crohn disease treated with infliximab in conjunction with azathioprine or 6-MP.

**IL-1 Inhibition**

Plasma IL-1 levels are increased in patients with active inflammation (see Chapter 34). In addition to the naturally occurring IL-1RA, several IL-1RAs are in development, and a few have been approved for clinical use.

**Anakinra** is an FDA-approved recombinant, nonglycosylated form of human IL-1RA for the management of joint disease in rheumatoid arthritis. **Anakinra** is also approved for cryoprotein-associated periodic syndromes (CAPS), a group of rare inherited inflammatory diseases associated with overproduction of IL-1 that include familial cold autoinflammatory and Muckle-Wells syndromes and for treatment of neonatal-onset multisystem inflammatory disease. It can be used alone or in combination with anti-TNF agents such as etanercept, infliximab, or adalimumab.

**Canakinumab** is an IL-1β mAb that is FDA approved for CAPS and active systemic juvenile idiopathic arthritis. **Canakinumab** is being evaluated for use in chronic obstructive pulmonary disease.

**Rilonacept,** a fusion protein that binds IL-1, is being evaluated for gout. IL-1 is an inflammatory mediator of joint pain associated with elevated uric acid crystals.

**Other Interleukin Antagonists**

**Tocilizumab,** an IL-6R, is FDA-approved for treatment of rheumatoid arthritis and systemic juvenile idiopathic arthritis; **silutezumab,** another IL-6 antagonist, is FDA approved for treatment of multicentric Castleman disease if the patient is HIV and human herpesvirus 8 negative. **Ustekinumab** is a human IL-12 and IL-23 antagonist indicated for the treatment of plaque psoriasis and psoriatic arthritis.

**Secukinumab** is a human anti-IL-17A antagonist indicated for treatment of plaque psoriasis.

Inhibition of Lymphocyte Function–Associated Antigen

**Efalizumab** is a humanized IgG1 mAb targeting the CD11a chain of LFA-1. Efalizumab binds to LFA-1 on lymphocytes and prevents LFA-1 interaction with intercellular adhesion molecule (ICAM), thereby inhibiting T-cell adhesion, trafficking, and activation. Efalizumab was approved for use in patients with psoriasis but has been withdrawn from the market because of excessive progressive multifocal leukoencephalopathy (Prater et al., 2014).

**Alefacept** is a human LFA-3–IgG1 fusion protein. The LFA-3 portion of alefacept binds to CD2 on T lymphocytes, blocking the interaction between LFA-3 and CD2 and interfering with T-cell activation. Alefacept is approved for use in psoriasis. Treatment with alefacept has been shown to produce a dose-dependent reduction in T-effector memory cells (CD45, RO+) but not in naive cells (CD45, RA+) (Vincenti and Kirk, 2008). This effect has been related to its efficacy in psoriatic disease and is of significant interest in transplantation because T-effector memory cells are associated with costimulation blockade-resistant and depletional induction-resistant rejection. Alefacept delays rejection in NHP cardiac transplantation and has synergistic potential when used with costimulation blockade or sirolimus-based regimens in NHPs (Vincenti and Kirk, 2008). A phase II multicenter study to assess the safety and efficacy of maintenance therapy with alefacept in kidney transplant recipients showed no difference from placebo controls (Rostaing et al., 2013).

**Cytokine Therapy: Interferon**

For a description of IFN induction and signaling and the major actions of IFN, see Chapter 34. **Interferon-β (IFN-β)** was among the first cytokines used for the treatment of autoimmune diseases, particularly MS. IFNs are endogenous regulatory cytokines that increase or decrease transcriptional initiation of hundreds of genes in a cell-dependent fashion with multiple mechanisms of action, including induction of IL-10. The different IFN-β formulations have modest therapeutic efficacy, decreasing the exacerbation rate in MS by approximately 30%. They are relatively safe; fatigue is the major side effect. There are multiple preparations of IFN-β in the market that are administered either by the intramuscular or subcutaneous routes. IFN-β preparations are usually used for MS and IFN-a/γ preparations are used for infections. Three IFN-β preparations are currently on the market: **Avonex** and **Rebif** are 1a formulations for MS; **Betaseron**, **Extavia** (1b preparations) and **peginterferon 1a** are indicated for relapsing MS. There are no significant differences between these IFN preparations, and as more efficacious drugs are now available, they should no longer be considered first-line drugs for the treatment of MS.

**Targeting B Cells**

Most of the advances in transplantation can be attributed to drugs designed to inhibit T-cell responses. As a result, T-cell–mediated acute rejection has become much less of a problem, while B-cell–mediated responses such as antibody-mediated rejection and other effects of donor-specific
antibodies have become more evident. Both biologics and small molecules with B-cell–specific effects now are in development for transplantation, including humanized mAbs to CD20 and inhibitors of the two B-cell–activation factors, BLYS and APRIL, and their respective receptors. Belimumab, a mAb that targets BLYS, was recently approved for use in patients with systemic lupus erythematosus.

The CD20 antibodies rituximab and acruximab deplete circulating mature B lymphocytes (though they may remain to some degree in lymph nodes), and positive results from clinical trials in patients with rheumatoid arthritis and MS strongly suggest that B cells play a critical part in disease pathogenesis. Genetic fine mapping studies demonstrated a potentially pathogenic role of B cells in MS and rheumatoid arthritis that were not limited to antibody production. In particular, a definitive genetic modeling study pointed to the crucial role of B cells as APCs (Farh et al., 2015).

Tolerance

Immunosuppression has concomitant risks of opportunistic infections and secondary tumors. Therefore, the ultimate goal of research on organ transplantation and autoimmune diseases is to induce and maintain immunological tolerance, the active state of antigen-specific nonresponsiveness (Krensky and Clayberger, 1994). Tolerance, if attainable, would represent a true cure for conditions discussed previously in this section without the side effects of the various immunosuppressive therapies. The calcineurin inhibitors prevent tolerance induction in some, but not all, preclinical models. In these same model systems, sirolimus does not prevent tolerance and may even promote tolerance (Kawai et al., 2014; Krensky and Clayberger, 1994). In experimental animals, sirolimus promotes regulatory T cells, a subtype of T cells shown to suppress all immunity, and promotes tolerance. Studies in kidney transplant recipients showed that sirolimus spared regulatory T cells in the periphery, unlike calcineurin inhibitors, which reduced their percentage (Segundo et al., 2006).

Costimulatory Blockade

Inhibition of the costimulatory signal has been shown to induce tolerance (Figure 35–4).

Costimulatory Blockade

Abatacept is a fusion protein (see previous discussion) that contains the binding region of CTLA4 (CD152), which is a CD28 homolog, and the Fc region of the human IgG1. CTLA4-Ig competitively inhibits CD28 binding to CD80 and CD86 and thus activation of T cells. CTLA4-Ig is effective in the treatment of rheumatoid arthritis in patients resistant to other drugs.

A second costimulatory pathway involves the interaction of CD40 on activated T cells with CD40 ligand (CD154) on B cells, endothelium, or APCs (see Figure 35–4). Among the purported activities of anti-CD154 antibody treatment is the blockade of B7 expression induced by immune activation. Two humanized anti-CD154 mAbs have been used in clinical trials in renal transplantation and autoimmune diseases. The development of these antibodies, however, is on hold because of associated thromboembolic events. An alternative approach to block the CD154-CD40 pathway is to target CD40 with mAbs. These antibodies are undergoing trials in non-Hodgkin lymphoma but are also likely to be developed for autoimmune and transplantation.

Donor Cell Chimerism

A promising approach is induction of chimerism (coexistence of cells from two genetic lineages in a single individual) by first dampening or eliminating immune function in the recipient with ionizing radiation, drugs such as cyclophosphamide, or antibody treatment and then providing a new source of immune function by adoptive transfer (transfusion) of bone marrow or hematopoietic stem cells. On reconstitution of immune function, the recipient no longer recognizes new antigens provided during a critical period as “nonself.” Such tolerance is long lived and less likely to be complicated by the use of calcineurin inhibitors.

Antigens

Specific antigens induce immunological tolerance in preclinical models of diabetes mellitus, arthritis, and MS. In vitro and preclinical in vivo studies demonstrated that one can selectively inhibit immune responses to specific antigens without the associated toxicity of immunosuppressive therapies. With these insights comes the promise of specific immune therapies to treat an array of immune disorders from autoimmunity to transplant rejection (Riedhammer and Weissert, 2015). To date, this approach has only worked in animal models of autoimmune disease.

Soluble HLA

In the precytosporine era, blood transfusions were shown to be associated with improved outcomes in renal transplant patients. These findings gave rise to donor-specific transfusion protocols that improved outcomes. After the introduction of cyclosporine, however, these effects of blood transfusions disappeared, presumably due to the efficacy of this drug in blocking T-cell activation. Nevertheless, the existence of tolerance-promoting effects of transfusions is irrefutable. It is possible that this effect is due to HLA molecules on the surfaces of red blood cells, other cells, or peptides corresponding to linear sequences of HLA molecules can induce immunological tolerance in animal models via a variety of mechanisms (Murphy and Krensky, 1999).

Immunotherapy for Multiple Sclerosis

Clinical Features and Pathology

Multiple sclerosis is a genetically mediated demyelinating inflammatory disease of the CNS white matter, characterized by mononuclear cell infiltration into the white matter with relative demyelination to axonal loss. Dense meningeal infiltrates are found in the subarachnoid spaces of patients, and these infiltrates are intimately associated with subpial demyelination, neuronal and glial cell damage, oligodendrocyte loss, cortical atrophy, and parenchymal microglial activation in the outer cortical layers. Inflammatory cortical demyelination occurs early in MS, preceding the appearance of classic white matter plaques with neurodegenerative changes, including oligodendrocyte loss, reactive astrocytosis, and axonal and neuronal injury within these cortical plaques on a background of inflammation. MS may be episodic or progressive and occurs with prevalence increasing from late adolescence to 35 years of age and then declining. MS is 3-fold more common in females than in males and occurs mainly in higher latitudes of the temperate climates. Epidemiologic studies suggest a role for environmental factors in the pathogenesis of MS, including low vitamin D, smoking, increases in body mass index, and high salt intake (Ransohoff et al., 2015).

Genome-wide association studies have identified genetic variants associated with MS susceptibility (International Multiple Sclerosis Genetics Consortium, et al., 2007), now with 200 variants identified. Although each of these contributes only a small increase in the complex phenotype of disease risk, the biological functions associated with individual allelic variants have been striking. Many of these variants fall within specific signaling cascades, which suggests that alterations in pathways—rather than independent genes—might be useful in predicting response to therapy. Over half of genetic variants associated with MS risk are also found in other putative autoimmune diseases, and risk alleles are primarily associated with genes that regulate immune function. Approximately 60% of probable causal variants mapped to HLA alleles. A number of these variants are dependent on the HLA type, with HLA-DRB1 conferring risk in many populations.

Genome-wide association studies have identified genetic variants associated with MS susceptibility (International Multiple Sclerosis Genetics Consortium, et al., 2007), now with 200 variants identified. **Pharmacotherapy**

There have been major advances in the treatment of MS. Table 35–3 summarizes current immunomodulatory therapies for MS. Specific therapies are aimed at resolving acute attacks, reducing recurrences and exacerbations, and slowing the progression of disability. MS exacerbations are treated with 3 to 5 days of 1000 mg of intravenous methylprednisolone, as oral prednisone alone is an ineffective treatment that increases the risk of new attacks. The so-called first-generation (but not necessarily "first-line") drugs include a variety of IFN-β (discussed previously in Cytokine Therapy) and random polymers that contain amino acids commonly used as MHC anchors, and TCR contact residues have been proposed as possible "universal altered peptide ligands." Glatiramer acetate (GA), a random-sequence polypeptide consisting of four amino acids (alanine [A], lysine [K], glutamate [E], and tyrosine [Y]) with an average length of 40–100 amino acids, binds efficiently to MHC class II DR molecules in vitro. In clinical trials, GA, administered subcutaneously to patients with relapsing-remitting MS, decreased the rate of exacerbations by about 30%, similar to the efficacy of IFN-β. In vivo administration of GA induces highly cross-reactive CD4+ T cells that are immune deviated to secrete anti-inflammatory Th2 cytokines such as IL-4 and IL-13. Administration of GA also prevents the appearance of new lesions detectable by MRI (Duda et al., 2000). This represents one of the first successful uses of an agent that ameliorates autoimmune disease by altering signals through the TCR complex. The long-term treatment of patients with MS is in transition, having moved from the use of first-era therapies of IFN-β and GA to more effective treatments. The anti-CD20 B cell depletion therapy with ocrelizumab is currently the most efficacious treatment (Hauser et al., 2017) and should in most instances be considered as a first line therapy. There is no rationale for the use of step therapy with IFN-β and GA before using the more effective drugs such as ocrelizumab and natalizumab.

The mAb natalizumab, directed against the adhesion molecule α4 integrin, antagonizes interactions with integrin heterodimers containing α4 integrin, such as α4β1 integrin that is expressed on the surface of activated lymphocytes and monocytes. An interaction of α4β1 integrin with vascular cell adhesion molecule 1 is critical for T-cell trafficking from the periphery into the CNS; blocking this interaction has been highly effective in inhibiting disease exacerbations.

Similarly, the S1P agonist fingolimod (mechanism discussed previously) is FDA-approved as a first-line therapy in MS, decreasing the exacerbation rate by about 50%. Use of natalizumab is associated with the development of progressive multifocal leukoencephalopathy, and availability is limited to a special distribution program (Touch) administered by the manufacturer that dictates measurement of JCV antibodies. Patients negative for JCV are often recommended to begin natalizumab, while JCV-positive persons are tested for VZV to evaluate fingolimod treatment. If the result is positive, indicating VZV immunity, fingolimod can be begun. If not, fingolimod treatment should follow VZV immunization. Regarding safety, natalizumab seems to be safe in patients negative for JCV antibody. In patients with cardiac issues—particularly with bundle branch blocks—fingolimod should be avoided.

Dimethyl fumarate appears to have multiple immunomodulatory effects and is an activator of nrf2 that mediates antioxidative response. In two pivotal phase 3 trials, dimethyl fumarate reduced relapse rates by about 50% as compared with placebo, with a significant reduction of gadolinium-enhanced lesions as well as T2 lesions on MRI. The drug seems to be safe, although gastrointestinal side effects can occasionally cause difficulties. Monoclonal antibodies directed against CD52 (alemtuzumab) were recently approved for relapsing-remitting MS (discussed previously). While it appears to be highly effective and long lived in terms of response, secondary autoimmune responses that emerge in patients with MS but

*Rankings are estimated on the basis of clinical trials, postapproval studies, and few head-to-head comparisons. The factors that determine drug efficacy in any individual patient are largely undefined, and good clinical judgment is essential for treatment selection. For details, see Ransohoff et al., 2015.*
not in those with CLL are thyroiditis and, more rarely, idiopathic thrombocytopenic purpura. The anti-CD20 antibody **ocrelizumab** has recently completed a phase 3 trial and has the most dramatic efficacy in treating MS, leading to FDA approval. It is now considered a first line drug in the treatment of relapsing remitting MS.

With all of these agents, the earlier in the course of MS that they are used, the more effective they are in preventing disease relapses. What is not clear is whether any of these agents will prevent or diminish the later onset of secondary progressive disease, which causes more severe disability.

Drugs Therapeutic Uses Clinical Pharmacology and Tips

Glucocorticoids

- Prednisone
  - The liver converts prednisone to prednisolone.
  - Prevent and treat transplant rejection, treat GVHD in bone marrow transplant, autoimmune disease, rheumatoid arthritis, ulcerative colitis, multiple sclerosis, systemic lupus erythematosus.
  - Broad effects on cellular immunity:
    - Affects transcription of many genes; ↓ NF-κB activation, ↓ pro-inflammatory cytokines IL-1 and IL-6.
    - ↓ T-cell proliferation, cytotoxic T-lymphocyte activation and neutrophil and monocyte function.
    - Can cause ↑ blood glucose, hypertension, Cushingoid habitus, ↑ weight, ↑ risk of infection, osteoporosis, glaucoma, cataracts, depression, anxiety, psychosis.
    - Long-term treatment ⇒ adrenal suppression; withdraw slowly on alternate days.
- Prednisolone
  - Rheumatoid arthritis, uveitis, ulcerative colitis, multiple sclerosis, vasculitis, sarcoidosis, systemic lupus erythematosus.
  - As above.
- Methylprednisolone
  - Systemic lupus erythematosus, multiple sclerosis.
  - As above.
- Dexamethasone
  - Rheumatoid arthritis, idiopathic thrombocytopenic purpura.
  - As above.
Calcineurin Inhibitors

- Cyclosporine
  - Transplant rejection prophylaxis, transplant rejection rescue therapy, rheumatoid arthritis, psoriasis and other skin diseases, xerophthalmia.
  - Use algorithms to delay dosing until renal function OK in kidney transplant patients.
  - Monitor C_p to avoid side effects.
  - Side effects: tremor, hallucinations, drowsiness, coma, nephrotoxicity, hypertension, hirsutism, hyperlipidemia, gum hyperplasia.
  - Metabolized by CYP3A ⇒ drug interactions.
  - Severe interactions with antiarrhythmics.
- Tacrolimus
  - Transplant rejection prophylaxis, transplant rejection rescue therapy.
  - GI absorption is incomplete and variable.
  - Side effects include nephrotoxicity, neurotoxicity, GI complaints, and hypertension.
  - Glucose intolerance and diabetes mellitus.
  - Monitor blood levels to avoid nephrotoxicity.

Antiproliferative and Antimetabolic Agents

- Azathioprine
  - Purine metabolism inhibitor, adjunct for prevention of organ transplant rejection, rheumatoid arthritis.
  - Renal clearance has little effect on efficacy or toxicity.
  - Side effects include bone marrow suppression (leukopenia > thrombocytopenia > anemia).
  - Susceptibility to infections, hepatotoxicity, alopecia, GI toxicity.
  - Avoid allopurinol.
- Mycophenolate mofetil
  - Purine metabolism inhibitor, prophylaxis of transplant rejection, used off label for systemic lupus erythematosus, multiple sclerosis, sarcoidosis.
  - Side effects include GI (diarrhea and vomiting) and hematologic (leukopenia, pure red cell aplasia) problems.
  - Contraindicated in pregnancy.
- Sirolimus
  - mTOR inhibitor, prophylaxis of organ transplant rejection, incorporated into stents to inhibit occlusion.
  - Monitor blood levels.
  - Hyperlipidemia.
  - Anemia, leukopenia, thrombocytopenia.
  - GI effects, mouth ulcers, hyperkalemia.
  - Anticancer effects.
  - Metabolized by CYP3A; requires close attention to drug interactions.
- Everolimus
  - mTOR inhibitor, astrocytoma, breast cancer, kidney and liver transplant reception prophylaxis, pancreatic neuroendocrine tumor, renal angiomyolipoma, renal cell cancer.
  - Pharmacokinetics distinct from sirolimus.
  - Toxicity similar to sirolimus.
- Temsirolimus
  - mTOR inhibitor.
  - As above.
- Belatacept
  - Prevention of renal transplant rejection.
  - Due to an increased risk of post-transplant lymphoproliferative disorder predominantly involving the CNS, progressive multifocal leukoencephalopathy, and serious CNS infections, administration of higher than the recommended doses or more frequent dosing is NOT recommended.

Historical Perspective

The historical impact of infectious diseases is evident in the high mortality rates in young children and adults and the disruption that these diseases have caused in emerging societies. The rise of civilization in conjunction with the domestication of plants and animals permitted people to live in denser communities with each other and with their animals. Such proximity provided ideal breeding grounds for infectious pathogens, and their spread resulted in epidemics throughout the world.

As people began to question the underlying causes of disease and the apparent protection to reinfection afforded to some survivors of a disease, ideas of immunity and disease prevention were born, apparently as early as the 5th century.

The concept of immunity goes back at least to the 17th century when emperor K’ang of China documented his practice of variolation, or inoculation, of his troops and his own children with smallpox to confer protection from the disease (Hopkins, 2002). Variolation involved taking liquid from a smallpox pustule of an infected patient, cutting the skin of an uninfected person, and then introducing the inoculum. Records from the 18th century note that Africans brought to the U.S. as slaves bore scars from smallpox variolation and were under the belief that they were immune to the disease. Variolation against smallpox was also reported by Lady Mary Montagu during her time in Constantinople (1716–1718). Lady Montagu, herself a survivor of smallpox, reported that certain Turkish women would open a wound in healthy individuals and introduce the contents of a smallpox vesicle with a large needle, thereby providing a level of protection against smallpox. About 2%–3% died after variolation, whereas 20%–30% died from natural infection. Lady Montagu had herself and a son variolated and later had a daughter successfully variolated in London under the auspices of physicians of the Royal Society. Positive outcomes notwithstanding, fear of the procedure persisted.

Around the same time, in Boston, Cotton Mather and Dr. Zabdiel Boylston began a program of variolation against smallpox. The program met with general success but was opposed by many physicians, fearful that inoculation spread the disease and worried by deaths after inoculation (~2% of those inoculated). One Puritan religious leader, Edmund Massey, preached against inoculation, quoting from the book of Job (Job 2:7: “So Satan went forth from the presence of the Lord and smote Job with sore boils.”) and arguing that Satan was the prime practitioner of inoculation and that such diseases as smallpox were a necessary trial of faith or punishment for sins, the fear of which “is a happy restraint upon many people” (Gross and Sepkowitz, 1998). Medical practice in Boston has come a long way since that time.

In 1796, Edward Jenner, who coined the term vaccination, from vacca, Latin for “cow,” helped to advance vaccine safety. He tested the hypothesis that smallpox protection could be achieved by using cowpox, a nonfatal, self-limited disease in humans caused by a virus of the Poxviridae family that includes monkeypox and smallpox and that can spread from cows to
Abbreviations

ACIP: Advisory Committee on Immunization Practices
ADCC: antibody-dependent cell-mediated cytotoxicity
AID: activation-induced cytidine deaminase
aP: acellular pertussis
APC: antigen-presenting cell
ASD: autism spectrum disorder
AVA: anthrax vaccine adsorbed
BCG: bacille Calmette-Guérin
BCR: B cell receptor
CDC: Centers for Disease Control and Prevention
CoP: correlate of protection
cRM: cross-reactive material
DTaP: diphtheria and tetanus toxoids and acellular pertussis
DTP: diphtheria and tetanus toxoids and pertussis
EMA: European Medicines Agency
Fab: fragment, antigen-binding
Fc: fragment crystallizable
GBS: Guillain-Barré syndrome
H1N1: hemagglutinin type 1 and neuraminidase type 1
H2N2: hemagglutinin type 2 and neuraminidase type 2
H3N2: hemagglutinin type 3 and neuraminidase type 2
HA: hemagglutinin
HbOC: Haemophilus influenzae type b oligosaccharide conjugate
Hib: Haemophilus influenzae type b
HI: human immunodeficiency virus
HPV: human papillomavirus
IgG: immunoglobulin, class G
IIV: inactivated influenza vaccine
IOM: Institute of Medicine
IPV: inactivated poliovirus (vaccine)
JE: Japanese encephalitis
JE-MB: Japanese encephalitis mouse brain
JE-VC: Japanese encephalitis Vero cell
mCoP: mechanistic correlates of protection
MCV4: meningococcal vaccine 4
MeV: measles virus
MMR: measles-mumps-rubella
MMRV: measles-mumps-rubella-varicella
MVA: modified vaccinia Ankara
NA: neuraminidase
nCoP: nonmechanistic correlates of protection
PCV13: pneumococcal conjugate vaccine 13 valent
PRP: polyribosylribitol phosphate
PRP-OMPC: polyribosylribitol phosphate outer membrane protein conjugate
PRP-T: polyribosylribitol phosphate tetanus
RAG: recombination-activating gene
RSV: respiratory syncytial virus
SAE: serious adverse event
SAGE: Strategic Advisory Group of Experts
SIDS: sudden infant death syndrome
TB: Mycobacterium tuberculosis
Td: tetanus toxoid and reduced diphtheria toxoid
Tdap: tetanus toxoid, reduced diphtheria toxoid, acellular pertussis
VDJ: variable, diversity, joining
VLP: virus-like particle
VZV: varicella zoster virus
WHO: World Health Organization

Humans, Jenner infected a boy with cowpox pus from an infected milkmaid; the boy got mildly ill from cowpox, recovered, and when challenged with smallpox collected from scabs of a smallpox patient, was unaffected, showed no symptoms, and was fully protected against the disease. Thus, it was possible to inoculate against a disease using material from a related but less-harmful disease.

By the early to mid-19th century, vaccination was accepted widely, and governments in the U.S. and Europe began to require vaccination of children. As in our own era, there was organized resistance from antivaccine groups. There was also a sense that immunity waned with time, and revaccinations were introduced, producing a sustained diminution of smallpox.

The work of Pasteur and Koch established a link between microorganisms and disease and provided the scientific understanding to develop more specific vaccines. Preservatives (glycerol was an early additive) and refrigeration increased shelf life of vaccines and permitted their wider distribution. The cells of the immune system began to be identified around 1890, followed by the discovery of antibodies and hyperimmune serum and demonstration of the efficacy of adjuvants (aluminum was the first) to increase immunogenicity (Marrack et al., 2009). In the 1950s, freeze-drying became standard, permitting worldwide distribution of purified vaccines. Through the coordinating efforts of the WHO, smallpox was declared “eliminated” in 1979.

Other scourges were attacked by vaccination in the mid-20th century. One was polio, an incurable neurological disease causing muscle wasting, paralysis, and death if the diaphragm is affected. In 1955, Jonas Salk released a vaccine against poliovirus. The Salk vaccine, an inactivated virus preparation administered by injection, was followed in 1961 by the Sabin oral vaccine, which employs an attenuated poliovirus that provides immunity to all three types of poliovirus. As a result of the polio vaccines, the annual number of cases in the U.S. fell to 161 in 1961 from 35,000 in 1955 (Hinman, 1984). Eradication of polio depends on interruption of person-to-person transmission, which requires that a high percentage of the susceptible population be inoculated. Most adults in developed countries are immune, but when a significant fraction of children is unvaccinated, there is the potential for an outbreak because wild polioviruses circulate.

These fundamental observations and experiments paved the way for the modern vaccines that have reduced mortality and morbidity rates from infectious pathogens across the globe. Modern laboratory technologies have rendered vaccines safe and highly effective against infectious pathogens and virus-transforming cancers and against neoantigens on cancerous cells. Vaccination strategies are a public health success, as shown by the complete worldwide eradication of smallpox and the elimination of polio in the Americas in 1994, Europe in 2002, and South-East Asia in 2014, with remaining endemic cases only in Pakistan, Afghanistan, and Nigeria in 2016 according to WHO. In 2016, WHO and the Pan American Health Organization declared the Americas free of endemic measles, credited to immunization campaigns. The current recommendations for childhood vaccinations are summarized in Table 36–1. The issue of nonvaccinators is presented further in the chapter.

Vaccination Induces Development of Immunological Memory

The hallmarks of an immune response to pathogens are the recognition and activation of the innate immune response that limits pathogen spread when microbes breach the host’s natural protective barriers, such as the skin, the respiratory epithelium, or the GI epithelium. If the pathogen is not controlled, the innate immune system then recruits the humoral (antibody-secreting B cell) and cellular (T cell) arms of the adaptive immune response to specifically target and destroy the invading pathogen. Once the microbe is eliminated during this primary response, small numbers of pathogen-specific B and T cells survive long term, sometimes
for the entire life of the host, as memory B and T cells. These memory cells confer host protection against reinfection with the same pathogen. During a second response, memory cells use their specific antigen receptors to recognize the invading pathogen. This results in their activation and expansion to directly kill infected cells (via T cells) or generate antibodies (via B cells) that will neutralize the pathogen.

Vaccination technology takes advantage of this paradigm. As a means of generating immunological memory, uninfected individuals are given a controlled infection or exposed to antigen that elicits an immune response. When these vaccinated individuals are subsequently infected with these pathogens in their environment, the responses of their memory T and B cells outpace the invading microbes to neutralize and prevent their spread in a much more rapid and greater magnitude secondary response.

B cell clonal expansion results in the differentiation of long-lived memory B cells and emergence of shorter-lived plasma cells that produce antibodies. During the primary response, following the vaccination, B cells will undergo this differentiation process and will initially secrete IgM antibodies. IgM antibodies are large and provide some protection. Days after the response is initiated, B cells will undergo clonal selection and will produce IgG, which is a higher-affinity antibody with enhanced pathogen neutralization capacity.

Differentiated plasma cells can also produce other antibody classes, such as IgA, IgD, and IgE, that have unique functions. IgD can be expressed on the surface of B cells; its function continues to be investigated. IgA antibodies are concentrated in mucous secretions, breast milk, and tears. IgE antibodies are important in the elimination of parasitic infections. Because IgG antibodies have undergone a selection process that increases their affinity, these antibody types are the targets of vaccine design. Secondary responses after vaccination therefore elicit a faster and larger B-cell response, and these B cells primarily make IgG antibodies (Clem, 2011).

Cellular immunity involving both CD4+ and CD8+ T cells is also a target of vaccine design. Unlike B cells, T cells target intracellular pathogens that have infected host cells. CD4+ T cells or helper T cells, stimulate B cells to produce antibody. CD8+ T cells kill infected cells. Like B cells, antigen-memory T cells survive long term and provide protection for future encounters with their specific antigen.

### Immunization Strategies

Immunity can be achieved from either passive or active methods involving exposure to natural infection or through artificial human-made antigens. Individuals can develop antibodies from natural infection or after vaccination.

#### Passive

Passive immunity involves the transfer of preformed antibodies from an immune individual to a nonimmune individual to confer temporary immunity. An example of passive natural immunity is the transfer of antibodies from mother to fetus during pregnancy and through breast milk and colostrum consumed by an infant. These antibodies enter the body and provide a first line of defense to the fetus or infant, which otherwise has no immunity to any pathogen.

An example of artificial passive immunization is the injection of antivenom antibodies. Animals are immunized with venom antigen and their hyperimmunized serum is transfused into the patient. Antivenom can be monovalent, effective against one type of venom, or polyvalent and effective against venom from multiple species. An antivenom binds and neutralizes a toxin. Early administration after injury is critical because antivenom can halt but not reverse venom damage. Even though antivenom is purified, trace proteins remain, and these can trigger anaphylaxis or serum sickness in patients. Most antivenoms are administered intravenously but can also be injected intramuscularly against stonefish and redback spider venom. Antivenoms have been developed against venomous spiders, acarids, insects, scorpions, marine animals, and snakes. Passive immunization is used for a variety of toxins and infections; a list of available immunoglobulins is shown in Table 36–2.

#### Active

A natural infection that stimulates the immune response in uninfected individuals may lead to development of immunological memory and protection from reinfection, as in the case of infection with the MeV. This only occurs if the individual survives the primary infection, which is not always the case for viruses like measles, influenza, or ebola. Active immunization through injection of artificial antigens elicits a controlled immune response leading to the generation of immunological memory. This type of immunization, compared to natural infection, does not cause infectious disease or compromise the life of the individual. Thus, vaccine technologies through active stimulation of the immune system ensure that the individual survives and has protection against the pathogen in the natural environment.

### Vaccine Types

Vaccines are currently used to generate vaccines to prevent many infectious diseases and to deter infectious pathogens that cause cancer such as hepatitis viruses that can lead to hepatocellular carcinoma and HPVs, which can cause cervical, anal, vaginal, and penile cancers. Effective vaccines activate both the innate and the adaptive immune systems. There are many different types of vaccines, each with advantages and disadvantages. Vaccine design involves an understanding of the nature of the microbe, the tropism of the pathogen, and the practical need in certain regions of the world. The following section summarizes current methods used in vaccine design. For a list of vaccines approved by the U.S. Food and Drug Administration, see Table 36–3.

#### Live Attenuated

Live attenuated vaccines use a weakened form of a virus that contains antigens that appropriately stimulate an immune response. Such viruses have been passaged to reduce their virulence but retain immunogenic antigens that elicit strong humoral and cellular responses and the development of memory cells after one or two doses. A virus, for example, can be isolated...
### APPROVED VACCINES IN THE U.S.

**Toxoids**
- Tetanus and diphtheria toxoids adsorbed for adult use
- Tetanus toxoid adsorbed
- Tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine, adsorbed

**Bacterial polysaccharide**
- Meningococcal polysaccharide vaccine, groups A, C, Y, and W-135 combined
- Pneumococcal vaccine, polyvalent
- Typhoid Vi polysaccharide vaccine

**Bacterial conjugate vaccines**
- *Haemophilus b* conjugate vaccine (meningococcal protein conjugate)
- *Haemophilus b* conjugate vaccine (tetanus toxoid conjugate)
- Pneumococcal 7-valent conjugate vaccine (diphtheria CRM197 protein)
- Pneumococcal 13-valent conjugate vaccine (diphtheria CRM197 protein)
- Meningococcal (groups A, C, Y, and W-135) oligosaccharide diphtheria toxoid conjugate vaccine
- Meningococcal (groups C and Y and *Haemophilus b* tetanus toxoid conjugate vaccine
- Meningococcal (groups A, C, Y, and W-135) polysaccharide diphtheria toxoid conjugate vaccine
- Meningococcal group B vaccine

**Live bacterial**
- BCG live
- Typhoid vaccine live oral Ty21a
- Cholera vaccine live oral

**Inactivated bacterial**
- Plague vaccine

**Live Viral**
- Measles and mumps virus vaccine, live
- Measles, mumps, and rubella virus vaccine, live
- Measles, mumps, rubella and varicella virus vaccine, live
- Varicella virus vaccine, live
- Zoster vaccine, live
- Rotavirus vaccine, live, oral
- Rotavirus vaccine, live, oral, pentavalent
- Influenza vaccine, live, intranasal (quadrivalent, types A and types B)
- Adenovirus type 4 and type 7 vaccine, live, oral
- Yellow fever vaccine
- Smallpox (vaccinia) vaccine, live

**Inactivated or subunit viral**
- Poliovirus vaccine inactivated (human diploid cell)
- Poliovirus vaccine inactivated (monkey kidney cell)
- Hepatitis A vaccine, inactivated
- Hepatitis B (recombinant) vaccine
- Hepatitis A vaccine, inactivated, and Hepatitis B (recombinant) vaccine
- Influenza A (H1N1) 2009 monovalent vaccine
- Influenza virus vaccine, H5N1 (for national stockpile)
- Influenza A (H5N1) virus monovalent vaccine, adjuvanted
- Influenza virus vaccine (trivalent, types A and B)
- Influenza virus vaccine (quadrivalent, types A and B)
- Human papillomavirus bivalent (types 16, 18) vaccine, recombinant
- Human papillomavirus quadrivalent (types 6, 11, 16, 18) vaccine, recombinant
- Human papillomavirus 9-valent vaccine, recombinant
- Japanese encephalitis virus vaccine, inactivated
- Japanese encephalitis virus vaccine, inactivated, adsorbed
- Rabies vaccine
- Rabies vaccine adsorbed

from humans and then used to infect monkey cells. After several passages, the virus can no longer infect human cells but retains immunogenic capacity. These attenuated viruses can elicit a robust immune response because they are similar to the natural pathogen.

Several drawbacks exist with these vaccines. Because these are live viruses, they generally must be refrigerated to retain their activity. In remote areas of the world where refrigeration is not available, obtaining and storing this type of vaccine can be limiting. Because viruses can mutate and change in the host, it may be possible that viruses can become virulent again and cause disease, although the frequency of adverse reactions using these vaccines is very low. Furthermore, attenuated vaccines cannot be utilized in immune-compromised individuals (e.g., patients with HIV or cancer). In addition, these vaccines are usually not given during pregnancy. Measles, polio, rotavirus, yellow fever, and chickenpox viruses are examples of pathogens for which live attenuated vaccines have been generated. Attenuated vaccines for bacteria are more challenging to generate than for viruses because bacteria have more complex genomes; however, recombinant DNA technology can be utilized to remove virulence but retain immunogenicity. A vaccine against *Vibrio cholera* has been generated this way (currently not approved in the U.S.). A live attenuated vaccine for tuberculosis also has been developed.

**Inactivated**

Polio, influenza, and rabies viruses and typhoid and plague bacteria have been utilized to generate inactivated vaccines. Killing pathogens through the use of heat, radiation, or chemicals to inactivate them generates the antigenic starting materials. The dead pathogens can no longer replicate or mutate to their disease-causing state and thus are safe. These types of vaccines are useful because they can be freeze-dried and transported without refrigeration, an important consideration in reaching developing countries. A drawback with inactivated vaccines is that they induce an immune response that is much weaker than that induced by the natural infection; thus, patients require multiple doses to sustain immunity to the pathogen. In areas where people have limited access to healthcare, ensuring that these multiple doses are delivered on time can be problematic and may result in reduced immunity to the pathogen, as in the case of poliovirus endemic disease.

**Subunit Vaccines**

As with inactivated vaccines, subunit vaccines do not contain live pathogens; rather, subunit vaccines use a component of the microorganism as a vaccine antigen to mimic exposure to the organism itself. Subunit vaccines typically contain polysaccharides or proteins (surface proteins or toxoids). Compared to live attenuated vaccines, subunit vaccines induce a less-robust immune response. The selection of antigenic subunit and the design and development of the vaccine can be lengthy and costly because the pathogen’s subunit antigens and their combination must be thoroughly tested to ensure they elicit an effective immune response. Scientists can identify the more immunogenic antigens in the laboratory and manufacture these antigen molecules via recombinant DNA technology, producing recombinant subunit vaccines. For example, the hepatitis B vaccine is generated by the insertion into baker’s yeast of hepatitis B genes coding for selected antigens. The yeast cells express these antigens, which are then purified and used in making a vaccine. A drawback to these vaccines is that even though they elicit an immune response, immunity is not guaranteed. Subunit vaccines usually are considered safe because they have no live replicating pathogen present.

**Polysaccharides.** Polysaccharide subunit vaccines utilize polysaccharide (sugar) antigens to induce an immune response. Bacterial cell walls are composed of peptidoglycan polysaccharides that help pathogens evade the immune system. This evasion mechanism is highly effective in infants and young children, making them more susceptible to infection. Unfortunately, these polysaccharides are not very immunogenic. Furthermore, the vaccines produced to sugar antigens cause suboptimal immune responses that result in only short-term immunity. Meningococcal
infection caused by Neisseria meningitidis (groups A, C, W-135, and Y) and pneumococcal disease are polysaccharide subunit vaccines against bacterial pathogens. Conjugate subunit vaccines use a technology to bind polysaccharide from the bacterial capsule to a carrier protein, often diphtheria or tetanus toxoid. This sort of antigen combination can induce long-term protection in infants and adults. These vaccines provide protection against pathogens where plain polysaccharide vaccines fail to work in infants and also provide more long-term protection in young children and adults. The Haemophilus influenzae type b (Hib) and Pneumococcal (PCV7 valent, PCV10 valent, PCV13 valent) are conjugate subunit vaccines recommended for children (see Table 36–1). The meningococcal A vaccine used in Africa is also an example of a conjugate subunit vaccine.

Surface Protein Subunit Vaccines. T protein–based subunit vaccines utilize purified proteins from the pathogen to induce an immune response. Because these proteins may not be presented in native form (i.e., as in the live pathogen), antibodies generated against these antigens may not bind efficiently to the live pathogen. Acellular pertussis (aP) and hepatitis B vaccines are examples of protein-based subunit vaccines. The hepatitis B vaccine contains the hepatitis B virus envelope protein made as an antigen produced in yeast cell culture.

Toxoids. Pathogenic bacteria such as Clostridium tetani and Corynebacterium diphtheria induce disease (tetanus or diphtheria, respectively) through production of their toxins. Vaccines against these toxins, known as toxoid vaccines, are effective because they elicit an immune response that results in the production of antibodies that can bind and neutralize these toxins, preventing cell damage in the patient. Inactivated or killed toxins are used as the immunogen; however, because they are not highly immunogenic, they must be adsorbed to adjuvants (aluminum or calcium salts) to increase their capacity to stimulate the immune response. Toxoid vaccines are safe because they do not contain live pathogens. In addition, they are stable over a wide range of temperatures and humidities (Baxter, 2007).

DNA Vaccines
Sequencing the genome of a pathogen provides information that enables the production of a DNA vaccine against selected genetic material. A microbe's antigenic genes are selected and incorporated in synthetic DNA. Intramuscular or intradermal injection delivers this engineered DNA to APCs, which uptake the DNA and transcribe and translate it to produce antigenic proteins. These APCs present these antigens to both humoral and cellular immune system components to generate immunity. This type of vaccine poses no risk of infection, can easily be developed and produced, is cost-effective, is stable, and provides long-term protection (Robinson et al., 2000). Disadvantages include its limit to protein antigens and the possibility of generating tolerance to that antigen because of low immunogenicity, thereby rendering ineffective immunity.

Many of these vaccines are currently in experimental phases, but none has been licensed in the U.S. DNA vaccines for influenza virus, herpesvirus, flaviviruses like Zika virus, and others are in the early stages of development. A DNA vaccine against West Nile virus has been approved for veterinary use. Delivery platforms for enhancing efficacy of DNA vaccines (such as electroporation) are being developed. There is also an emerging research field to use RNA as a vaccine delivery platform.

Recombinant Vectors
A vector is a virus or bacterium that is used to deliver heterologous microbial genes to cells for expression in the vaccinee to elicit an immune response. Once the vector infects or transduces host cells, the selected antigens will be presented during the immune response to generate immunity. Both viruses and bacteria are being investigated as recombinant vectors for candidate vaccines. Virus vectors that have been used in candidate vaccines include many poxviruses (vaccinia virus, modified vaccinia Ankara, avian poxviruses, and others), a large number of adenoviruses (of both human and primate origin), and other families of viruses.

Immunoglobulins

Structure
Vaccination results in the expansion and differentiation of B cells into long-lived memory cells that provide long-term protection to secondary challenge, and plasma cells, which are immunoglobulin (antibody)–generating cells that produce large quantities of these proteins. Antibodies in the body are found in two forms, either membrane bound on B cells as BCRs that can deliver signals to activate and induce B-cell differentiation after antigen ligation or as soluble effector molecules that neutralize antigens throughout the body. Antibodies are heterodimeric proteins composed of two chains, the light and heavy chains. Both light and heavy chains contain variable regions in the N-terminal region of the protein that engage antigens. Naïve B cells express BCRs with low affinity to antigen. These BCRs can be selected through VDJ recombination via the activity of RAG enzymes. Antibody diversity is achieved through antigen-binding site region variation, combinatorial diversity of gene segments, and combination of light and heavy regions, an overall diversity program that can result in an antibody repertoire of potentially 109 to 1010 different molecules, ensuring that a unique B cell in the body will exist to recognize any foreign antigen. In addition to this diversity, antibodies also can undergo class-switch recombination in which the constant region of the heavy chain can be switched, based on cytokine signals by T cells, to tailor antibody specificity and function. It is this portion of the antibody that determines the five main isotypes: IgM, IgD, IgG, IgA, and IgE. These isotypes differ in size, Fc receptor binding, ability to fix complement, and appropriate isotypes for specific pathogens (Schroeder and Cavacini, 2010).

Antibody diversity can be further enhanced on antigen recognition by B cells and help from CD4+ T cells. B cells can further strengthen their antibody affinity by mutating their variable regions, and with repetitive antigen stimulation, the affinity of binding to antigen can increase further. This mechanism explains why some vaccines, like the one for hepatitis B, are most immunogenic when delivered in three doses. This repeated antigen stimulation induces somatic hypermutation of antibody variable genes to increase antibody efficacy. AID is a key enzyme in mediating class-switch recombination and somatic hypermutation. Human patients with defective AID suffer from hyper-IgM syndrome and are unable to class switch their antibodies, which makes them more susceptible to certain infections.

Manufactured antibodies can be used for passive immunization; for a list of available antibodies, see Table 36–4. Such monoclonal antibodies are biologicals that have become some of the most important drugs of our era. To date, monoclonal antibodies have been implemented most effectively for use in cancer immunotherapy and management of autoimmune diseases. Palivizumab is a humanized murine monoclonal antibody that is licensed for use in high-risk infants to prevent hospitalization due to RSV. As the cost of production of monoclonal antibodies continues to fall, more of these biologicals will likely be used for prophylaxis or treatment of infectious diseases.

Antibody Classes and Functions

Immunoglobulin M
The first antibody class expressed by B cells is IgM. IgM molecules are membrane-bound monomers found on circulating mature B cells. When mature B cells are antigen stimulated, they generate IgM pentamers that are secreted. IgM antibodies, also called natural antibodies, have low affinity as monomers, but their avidity can increase in their pentameric structure, which improves epitope binding to repeating antigens on pathogens. These antibodies are found at mucosal surfaces and constitute 10% of the antibody content of serum. These antibodies are associated with a primary immune response. IgM molecules function by coating their specific antigen to target the pathogen for destruction via phagocytosis or to induce complement fixation to kill the pathogen (Schroeder and Cavacini, 2010).

aNot approved in the E.U.
bNot approved in the U.S.
cInhibits the binding of the protective antigen to its membrane receptors, thereby preventing the intracellular entry of the anthrax lethal factor and edema factor, the enzymatic toxin components responsible for the pathogenic effects of anthrax toxin.

**Immunoglobulin D**

Like IgM molecules, IgD molecules are also expressed on naïve B cells that have not been activated by their specific antigen and thus have not undergone somatic hypermutation. They are expressed as monomers on the surface of B cells and can also be secreted; they represent less than 0.01% of the antibody in the serum (Schroeder and Cavacini, 2010). The exact function of this antibody is not fully known, but it can bind bacterial proteins through the constant region (Riesbeck and Nordstrom, 2006).

**Immunoglobulin G**

The IgG antibodies exist as monomers, represent about 70% of the antibody in circulation, and have been the most studied. They have the longest t½ of all subclasses and are generated with high affinity after affinity maturation. The constant region of the heavy chain can further lead to diversity in the structure of these antibodies to generate four subclasses: IgG1, IgG2, IgG3, and IgG4. These subclasses are named based on their concentrations in serum, with IgG1 the most abundant and IgG4 the least. IgG1, IgG2, and IgG3 subclasses can activate complement to opsonize pathogens, but IgG4 cannot. These antibodies can also differ in their ability and affinity to engage Fc receptors, which further enhances their effector functions. All IgG subclasses cross the placenta to provide passive immunity to the fetus.

Vaccines predominantly induce these antibody types, which become important during the secondary immune response to inactivate pathogens. Different subclasses are selected during the secondary antibody response. In designing vaccines, scientists must determine which antibody subclass will provide the optimal response. In addition to complement and opsonization, IgG antibodies can directly neutralize toxins and viruses (Schroeder and Cavacini, 2010).

**Immunoglobulin A**

The IgA antibody class is expressed as monomers or dimers and represents about 15% of the antibodies in serum, slightly higher than IgM antibodies. At mucosal surfaces, saliva, and breast milk, however, IgA antibodies are found at the highest concentrations (Woof and Mestecky, 2005). In late pregnancy and the early post-natal period, female mammary glands produce colostrum; more than half of the protein content of colostrum that breast-feeding neonates consume is IgA antibodies. IgA is primarily a monomer in the serum but a dimer at mucosal sites.

IgA antibodies have two subclasses, IgA1 and IgA2, that differ only slightly in their structures. IgA1 antibodies are longer than IgA2 antibodies and are therefore more sensitive to degradation. IgA2 is more stable and is found primarily in mucosal secretions, in contrast to IgA1, which predominates in serum. IgA antibodies work via direct neutralization of viruses, bacteria, and toxins to protect mucosal tissues. They prevent antigen binding to host cells that damage or infect them. IgA antibodies within cells may also prevent pathogen tropism. Even though IgA antibody do not lead to complement fixation, neutrophils can uptake them to mediate ADCC (Schroeder and Cavacini, 2010).

**Immunoglobulin E**

The IgE antibody class is present at the lowest serum concentration, less than 0.01% of circulating antibodies, and has the shortest t½. IgE binds to Fcε receptors with very high affinity. Langerhans and mast cells, basophils, and eosinophils express Fcε receptors that bind IgE antibodies. Fc receptor engagement also results in FcεR upregulation on bound cells. These antibodies recognize antigens on parasitic worms when they are cross-linked on granulocytes; the cells degranulate to release inflammatory mediators to destroy the parasite. IgE antibodies are also relevant in mediating allergic reactions by recognizing innocuous antigens, such as bee venom and peanut antigen.

Patients who develop allergic reactions generate memory B cells that produce IgE antibodies to specific antigens. The granulocytes become coated with IgE antibodies and on antigen reexposure such as a bee’s sting or peanuts, the antigen cross-links IgEs, leading to granulocyte...
degranulation, which can result in anaphylactic shock. Therapies are in development to generate and use antibodies against soluble IgE molecules to prevent their uptake by granulocytes. For a list of approved monoclonal antibodies, see Table 36–4.

**Specific Conventional Vaccines Recommended in the U.S.**

The CDC maintains tables listing currently recommended vaccinations for various susceptibilities throughout life. Next is a discussion of the properties and schedule of administration for the vaccinations recommended from birth toelder adulthood. The vaccines are grouped by the target type (bacterium, virus, etc.) and then by vaccine type, as discussed in the previous section. See Table 36–1 for infant and childhood vaccination schedules. For a complete list of the adult recommended immunization schedule, see Tables 36-5 and 36-6.

**Vaccines for Bacteria**

**Bacterial Toxoid Vaccines: Diphtheria and Tetanus**

**Tetanus Toxoid Vaccine.** Tetanus is a disease characterized by prolonged spasms and tetany caused by the toxin secreted by the bacterium *C. tetani*, which enters from environmental sources through wounds. Tetanus toxin enters the nervous system and by retrograde transport reaches the inhibitory interneurons of the spinal cord, where the active fragment cleaves synaptobrevin (see Figures 8–3 to 8–6), thereby inhibiting exocytosis from neurotransmitter from these nerve cells and resulting in uninhibited skeletal muscle contraction. The toxin is produced by deactivating toxin isolated from the bacterium using formaldehyde. Immunization usually begins at about age 2 months, as a component of the combination vaccine DTPa that is given to infants. Tetanus toxoid is included in several combination vaccine formulations. DTPa is the vaccine used in children younger than age 7; Tdap and Td, given at later ages, are booster immunizations that offer continued protection from those diseases for adolescents and adults. In these designations, upper- and lowercase letters represent the comparative quantity of antigen present. Thus, the shared uppercase T indicates there is about the same amount of tetanus toxoid in DTPa, Tdap, and Td. The uppercase D and P in the childhood formulation indicate that there is more diphtheria and pertussis antigen in DTPa than in Tdap or Td.

**Diphtheria Toxoid Vaccines.** Diphtheria is a disease caused by a secreted toxin of the aerobic gram-positive bacterium *C. diphtheria;* toxin production is under control of the bacterial systems, but the structural gene for toxin production is contributed by a β phage that infects all pathogenic strains of *C. diphtheria.* The β subunit of the toxin is an ADP-ribosylase; following its entry into a cell, it ADP-ribosylates eukaryotic elongation factor 2 (eEF-2) and thereby inhibits protein translation in human cells (Gill et al., 1973). The throat of the victim becomes swollen and sore during infection, and the toxin causes damage to myelin sheaths in the nervous system, leading to loss of sensation or motor control. The vaccine, which has been used for nearly 80 years, is a toxoid that is produced by treating toxin with formalin. The toxoid is used to immunize infants beginning at about 2 months, typically as part of the combination DTPa vaccine. The diphtheria toxin also has been detoxified genetically by introduction of point mutations that abrogate enzymatic activity but allow retention of binding activity; for instance, the mutant diphtheria toxin protein CRM197 is the protein carrier for a licensed Hib vaccine.

**Pertussis Vaccines.** Pertussis, or whooping cough, is a respiratory tract disease characterized by prolonged paroxysmal coughing and sometimes respiratory failure; it is caused by the gram-negative coccobacillus *Borde-tella pertussis.* The secreted pertussis toxin has an A subunit that, once in the cell cytosol, ADP-ribosylates the α subunit of the G protein that couples inhibitory GPCR signaling to adenyl cyclase to reduce cyclic AMP production. After ADP-ribosylation, Gi becomes inactive, and GPCR-mediated reduction of cyclic AMP production is abolished. The physiological sequelae of this action of pertussis toxin are thought to contribute to the constellation of symptoms of whooping cough. Routine vaccination typically begins as part of the childhood combination DTPa vaccine series. It is also appropriate to immunize healthy adults, adolescents, and pregnant mothers as pertussis does occur throughout life due to waning immunity. There are two licensed pertussis vaccines, the historical inactivated organism “whole-cell” vaccine used in the past in the U.S. and still in many other countries and a second “acellular” formulation that incorporates antigen fragments derived from the organism. Both vaccines are immunogenic and protective. The whole-cell vaccine appears to induce more durable immunity, but the acellular vaccine causes about a 10-fold lower rate of side effects such as fever or injection site pain and erythema. Most developed countries now use acellular pertussis vaccine to reduce the reactivity profile, but many other countries continue to use the whole-cell vaccine successfully because the response is equally efficacious and more durable and the vaccine is economical.

**Conjugated Bacterial Polysaccharide Vaccines**

**Haemophilus influenzae Type B Vaccine.** *Haemophilus influenzae* is a major cause of life-threatening childhood bacterial diseases, including bacular, preseptal and orbital cellulitis, epiglottitis, bacteremia with sepsis, and meningitis. Universal vaccination with the Hib vaccine has nearly eliminated these diseases in the U.S. The Hib vaccine is a polysaccharide-protein conjugate that confers immunity to the disease by inducing antibodies to the capsular polysaccharide PRP. The Hib polysaccharide has been conjugated to diverse proteins, including the mutant diphtheria protein CRM197 (a vaccine termed HibOC); the meningococcal group B outer membrane protein C (a vaccine termed PRP-OMP); and tetanospsasmin, which is a toxoid of the *C. tetani* neurotoxin (a vaccine termed PRP-T). The vaccines all exhibit a high level of safety and immunogenicity. Interestingly, widespread immunization not only reduces disease in those vaccinated, but also reduces nasal carriage of the bacterium, resulting in reduced transmission to even those not vaccinated and providing evidence of herd immunity.

**Streptococcus pneumoniae Vaccines.** The gram-positive encapsulated bacterium *S. pneumoniae* causes invasive diseases in infants and young children, including meningitis, bacteremia and sepsis, and pneumonia. There are myriad *S. pneumoniae* types, based on the capsular polysaccharide; thus, polyvalent vaccines are needed. Vaccines confer immunity by inducing type-specific antipolysaccharide antibodies. Two types of vaccines are available, polysaccharide and conjugate vaccines. The 23-valent polysaccharide vaccine contains long chains of capsular polysaccharides that are collected from inactivated bacteria. Polysaccharide vaccine is used in children older than 2 years and in at-risk adults. PCVs have been developed, and increasing numbers of serotypes have been incorporated over time. The combined 13 serotypes in PCV13 protect against most invasive disease in the U.S. Infants are given a primary series of PCV13 at ages 2, 4, and 6 months, with a booster at 12 to 15 months.

**Neisseria meningitidis Vaccines.** *Neisseria meningitidis* is a significant cause of invasive bacterial disease in childhood, causing sepsis and meningitis. As with *S. pneumoniae*, there are diverse types of polysaccharide; thus, type-specific capsular polysaccharide antibodies meditate protection against invasive disease. Therefore, multivalent vaccines are required. A licensed quadrivalent polysaccharide vaccine protects against four subtypes of meningococcus—designated A, C, Y, and W-135. The polysaccharide vaccine works only in children older than 2 years. A tetra-valent meningococcal conjugate vaccine, also containing the A, C, Y, and W-135 subtypes, is used in persons 9 months to 55 years of age. In 2013, the European Commission licensed a four-component, protein-based meningococcal B vaccine (incorporating HbP, NadA, NHBA, and PorA P1.4 proteins) to prevent septicaemia and meningitis.

**Vaccines for Viruses**

**Poliovirus Vaccines**

Polio is a characterized by acute flaccid paralysis, against which the WHO and others are conducting a worldwide eradication campaign. There are two types of poliovirus vaccines in use. The first is a live attenuated oral
Vaccine in use since the early 1960s (the “Sabin vaccine”), containing attenuated poliovirus types I, II, and III, produced in monkey kidney cell tissue culture. The vaccine replicates in the intestine and induces systemic and mucosal immunity, but also is shed in the stool, sometimes transmitting to close contacts. Infection of most close contacts contributes to herd immunity in the human population. Rarely (about one case per million doses), partial revertant viruses occur that cause vaccine-associated paralytic poliomyelitis in contacts. In many parts of the world, live poliovirus vaccine is still used. The last known case of naturally acquired poliovirus disease acquired in the U.S. occurred in 1979; the U.S. discontinued use of the live vaccine in 2000. Live poliovirus vaccine is contraindicated in subjects with primary immunodeficiency. Pregnant women and children with symptomatic HIV infection should receive IPV vaccine.

The second type of vaccine is a killed virus preparation called IPV (the “Salk vaccine”). Killed vaccine induces mainly humoral immunity but still exhibits excellent efficacy against disease. IPV does not transmit virus to contacts and does not cause vaccine-associated paralysis. An enhanced-potency IPV vaccine has been available since 1998, and this IPV preparation is now a component of some combination vaccines.

Measles Virus Vaccines
The current measles vaccine is a live attenuated strain given subcutaneously. A live, “more attenuated” preparation of the Enders-Edmonston virus strain (designated the “Moraten” strain) is the MeV vaccine currently used in the U.S. Vaccination is initiated at 12 to 15 months of age in the U.S. because transplacentally acquired maternal antibodies inhibit immunogenicity of vaccine in the first year of life.

Mumps Virus Vaccine
Mumps virus causes a febrile illness most commonly associated with inflammation of the parotids and sometimes with more severe conditions, including aseptic meningitis. A live attenuated virus vaccine has been used exclusively since the 1970s. The Jeryl-Lynn vaccine (from a mixture of two strains) was isolated from the throat of the daughter of Maurice Hilleman, a noted vaccine developer. The vaccine is typically given as a component of the combination MMR or MMRV vaccine at 12 to 15 months of age.

Rubella Virus Vaccine
Rubella virus, a member of the Togaviridae family, is spread by respiratory droplets and causes a mild infection with viremia. Rubella is harmful only to fetuses, and the effects can be devastating. A rubella infection during pregnancy can cause miscarriage, preterm birth, stillbirth, or various birth defects. The risks decrease as pregnancy progresses. The main goal of rubella immunization is to prevent congenital rubella syndrome. The live attenuated rubella virus vaccine is given subcutaneously, now usually as a component of MMR or MMRV vaccine, beginning between 12 and 15 months of age. The live rubella virus vaccine strain RA 27/3 is grown as a component of MMR or MMRV vaccine, beginning between 12 and 15 months of age. The live rubella virus vaccine strain RA 27/3 is grown in human diploid cell culture. In the U.S., universal immunization (both boys and girls) is used to reduce infection of pregnant women. As a result, rubella and congenital rubella syndrome have been eliminated in the U.S. Rubella vaccine is part of MMR or MMRV combination vaccines for universal immunization starting at 12 to 15 months, followed by a booster dose at school entry (~5 to 6 years).

Varicella Zoster Virus Vaccine
Varicella zoster virus is one of the most infectious among agents that affect humans. It is spread by the respiratory route by small aerosol particles (cough, sneeze, etc.). Infection causes a febrile syndrome with vesicular rash, sometimes complicated by pneumonia or invasive bacterial skin disease. Congenital varicella syndrome can occur if varicella infection occurs during pregnancy. The vaccine used is the Oka strain of live attenuated VZV attenuated by sequential passage in cell monolayer cultures; it was licensed for universal immunization in the U.S. in 1995. The virus in the Oka/Meck vaccine in current use in the U.S. was further passaged in MRC-5 human diploid-cell cultures. The vaccine is often given as a part of the combination MMR vaccine.

Hepatitis A Virus Vaccines
Hepatitis A virus infection causes acute liver disease after transmission by the fecal-oral route. An inactivated vaccine is recommended for all children, starting at 1 year of age. Two hepatitis A vaccines and one hepatitis A vaccine/hepatitis B combo vaccine are licensed in the U.S. The vaccine is given as a two-dose series.

Hepatitis B Virus Vaccines
Hepatitis B virus is transmitted between people by contact with blood or other bodily fluids, including by sexual contact and maternal transfer to fetus or infant. Hepatitis B virus can cause a life-threatening and sometimes chronic liver disease. All infants receive the hepatitis B vaccine. When the mother has active infection, the neonate is treated with both the vaccine and hepatitis B immune globulin. The vaccine is a recombinant protein produced in yeast that is the protective antigen, hepatitis B surface antigen (see also Chapter 63).

Rotavirus Vaccines
Throughout the world, rotavirus is the most common cause of dehydrating diarrhea in infants. Four or five types (based on the surface proteins) cause severe disease. An early live attenuated vaccine (Rotashield) was withdrawn after association with intussusception (a segmental, telescoping collapse of the intestine). Two similar vaccines are now used that are safe and immunogenic. One is an oral pentavalent human-bovine reassortant rotavirus vaccine (containing five reassortant rotavirus strains developed from human and the Wistar Calf 3 bovine parent rotaviral strains) first licensed in the U.S. in 2006 (Rotarix). This vaccine is administered in a three-dose schedule, at 2, 4, and 6 months of age. Another oral live attenuated rotavirus vaccine licensed in the U.S. is based on a single attenuated human strain (Rotarix) using a two-dose schedule, beginning at 2 months of age. Rotavirus vaccines are used for universal immunization during infancy, with care to keep the initiation of the two- or three-dose series at a young age, as the rare rotavirus-associated intussusception risk with infection appears slightly higher at older ages.

Influenza Virus Vaccines
The orthomyxovirus influenza virus is a respiratory virus spread person-to-person by large-particle aerosols and fomites. The virus circulates in humans in two major serotypes (types A and B); two distinct A subtypes, designated H1N1 and H3N2, currently cause disease (“the flu”) in humans. Current seasonal influenza vaccines are trivalent, including A/H1N1, A/H3N2, and B antigens, or quadrivalent with a second type B antigen. Experimental vaccines are being tested for some avian influenza viruses (such as A/H5N1 and A/H7N9) that have infected humans and have pandemic potential. During each annual seasonal epidemic, point mutations occur in genes encoding the hemagglutinin and neuraminidase proteins, which are the principal targets for protective antibodies. This antigenic drift in circulating influenza strains has led to a process in which regulatory officials and manufacturers adjust the virus antigens in influenza vaccines every year. Occasionally, the segmented virus genome reassorts during coinfection of an animal with a human and an avian virus, a new virus arises (antigenic shift), and a pandemic occurs. Major worldwide pandemics occurred in 1918 (H1N1), 1957 (H2N2), 1968 (H3N2), and 2009 (a novel H1N1). Major adjustments of vaccines must be made in such instances.

Two principal types of influenza vaccines are licensed at present, inactivated vaccine and live attenuated virus vaccine. The inactivated vaccine is prepared by treating wild-type viruses prepared in eggs or cell culture with an inactivating agent. Inactivated vaccine often prevents more than half of serious influenza-related disease when the viruses chosen for the seasonal vaccine antigenically match the eventual epidemic virus well. The vaccine is most effective at preventing severe respiratory disease and influenza-related hospitalizations.

All persons aged 6 months and above should be vaccinated. Those at most risk of severe disease and in most need of vaccine are infants, young children, people older than 65 years, pregnant women, and those with chronic health conditions or immunodeficiency. This vaccine is contraindicated in those who have had a life-threatening allergic reaction after a
dose of influenza vaccine or have a severe allergy to any component of the vaccine, some of which contain a small amount of egg protein. Some people with a history of Guillain–Barré syndrome should not receive this vaccine. The vaccine is usually given as a single dose each year, although children 6 months through 8 years of age may need two doses during a single influenza season. Some IIVs contain a small amount of the preservative thimerosal (see Preservatives, Including Thimerosal). Although any association with developmental disorders has been disproven, public concern about this topic has led to the development of thimerosal-free IIVs.

The second principal type of influenza vaccine is a trivalent or quadrivalent live attenuated virus vaccine that is administered topically by nasal spray. New vaccines are prepared each year to address antigenic drift by reassorting genes encoding the current HA and NA antigens with a virus genetic background containing internal viral genes with well-defined attenuating mutations. The vaccine is licensed in the U.S. for persons 2 to 49 years of age. In some pediatric studies, the live attenuated vaccine appeared to provide a higher level of protection than inactivated vaccine; however, CDC vaccine effectiveness data from the influenza seasons in 2013–2016 in the U.S. indicated that the quadrivalent live attenuated vaccine did not demonstrate statistically significant effectiveness in children 2–17 years of age. Therefore, the CDC provided an interim recommendation that the vaccine should not be used in any setting in the U.S. for the 2016–2017 influenza season. Practitioners should check regularly for updated guidelines from the CDC on this point.

**Human Papillomavirus Vaccines**

Human papillomaviruses cause nearly all cases of cervical and anal cancer and a majority of oropharyngeal cancers. Most such cancers are caused by just two of the many HPV serotypes, types 16 and 18. Remarkably, even though the virus cannot be grown efficiently in culture, effective HPV vaccines were developed using VLPs that are formed by HPV surface components. All licensed HPV vaccines protect against at least these two types and some protect against four or nine types of HPV, with effectiveness against vaginal and vulvar cancers in women, as well as most cases of anal cancer and genital warts in both females and males. HPV vaccines are recommended for all 11- and 12-year-olds to protect against HPV infection and for women 13 to 26 years old and men 13 to 21 years old not previously vaccinated. HPV vaccination is also recommended for any man who has sex with a man. The vaccines are given in a three-dose regimen on a schedule of 0, 1-2, and 6 months.

**Maternal Immunization**

Maternal immunization during pregnancy can enhance newborn protection after birth by providing passive immunity to the neonate. Immunizing pregnant mothers is safe and protects the child from deadly infectious pathogens early in life when the immune system is not fully developed. One of the most successful maternal immunization protocols involves injection of tetanus toxoid to stimulate the production of IgG antibodies that have high neutralizing capacity and can cross the placenta. Vaccines for group B Streptococcus, Hib, RSV, Streptococcus pneumoniae, Bordetella pertussis, and trivalent IIVs have been tested in pregnant women. For a complete list of maternal vaccines, see Table 36–7.

**Vaccines for Travel**

International travelers should ensure that their vaccination status is current for conventional vaccines, including diphtheria, tetanus, pertussis, hepatitis A and B, and poliovirus; exposures to these agents may be more common in some international settings. There are additional vaccines that may be of benefit as preventive vaccines; these are listed next.

are licensed in the U.S.; an inactivated mouse brain–derived JE vaccine (JE-MB) for use in travelers aged 1 year and older and an inactivated Vero cell culture–derived JE vaccine (JE-VC) for persons aged 17 years or older.

**Yellow Fever Virus Vaccine**

Yellow fever is a mosquito-borne flaviviral disease with a wide range of systemic symptoms. In severe cases, the disease causes hepatitis, hemorrhagic fever, and death. The CDC recommends this vaccine for children older than 9 months and adults who will be traveling to high-risk areas. There is generally a requirement for documentation of vaccination for travel to and from infected areas. The vaccine is a live attenuated virus vaccine that has been used successfully for many decades. For international travel, yellow fever virus vaccine must be approved by WHO and must be administered by an approved yellow fever vaccination center that can provide both vaccination and a validated International Certificate of Vaccination. The vaccine should be given at least 10 days before travel to an endemic area. Generally, a single dose suffices.

**Typhoid Vaccine**

Typhoid fever is an acute illness caused by the bacterium *S. typhi*, which is transmitted by ingestion of contaminated water or food. Typhoid vaccination is recommended for international travelers who will visit rural areas or villages that have inadequate sanitation. Symptoms include fever, headache, anorexia, and abdominal discomfort; the disease can be fatal. Treatment is challenging, and there has been an increase in the number of drug-resistant strains of *S. typhi* over the last several decades. There are two vaccines available to prevent infection: a single-dose, injectable, inactivated typhoid vaccine and an oral live typhoid vaccine that is taken in a four-dose course.

**Rabies Virus Vaccine**

Rabies is caused by a lyssavirus transmitted to humans from the bite of infected mammals; the untreated infection is nearly always fatal in humans. Rabies vaccination is used in two ways, first as a preventive vaccine prior to exposure and second as a postexposure intervention to prevent progression to fatal disease. Candidates for preexposure vaccination are people at high risk of exposure to natural rabbits (veterinarians, animal handlers, spelunkers, et al.) or to laboratory strains or tissues (such as those involved in production of rabies biologicals). Preventive vaccination should be offered to international travelers who are likely to come in contact with animals in parts of the world where rabies is common (see CDC website). The vaccine is given in a three-dose series on days 0, 7, and 28. For those who may be repeatedly exposed to rabies virus, periodic testing for immunity is recommended, and booster doses can be administered as needed to maintain immunity. Postexposure vaccination is used in emergency settings following a bite or close exposure to an animal that may be rabid. In this setting, the vaccine is given in a four-dose series on days 0, 3, 7, and 14, concomitant with two injections of rabies immune globulin on day 0, one locally into the bite site and a second in an intramuscular injection for systemic administration of antibodies. A bite victim who has been previously vaccinated should receive two doses of rabies vaccine on days 0 and 3 but does not need rabies immune globulin.

**Specialty Vaccines**

There are limited-use vaccines that are offered in special circumstances to at-risk persons.

**Anthrax Vaccine**

Anthrax vaccine is offered to certain at-risk adults 18 to 65 years of age, including some members of the U.S. military, laboratory workers who work with anthrax, and some veterinarians or other individuals who handle animals or animal products. Anthrax is a serious disease in animals and human caused by *Bacillus anthracis*. People can contract anthrax from contact with infected animals or animal products. Usually, the cutaneous infection causes ulcers on the skin and systemic symptoms, including fever and malaise; up to 20% of untreated cases are fatal. Inhaled spores of *B. anthracis* usually cause fatal infection. AVA, given as multiple booster injections, protects against cutaneous and inhalation anthrax acquired by exposure on skin or by inhalation. The CDC recommends anthrax intramuscular booster shots 4 weeks, 6 months, 12 months, 18 months, and then annually.

**Vaccinia Virus (Smallpox Vaccine)**

Vaccinia vaccine is a live attenuated orthopoxvirus vaccine developed by multiple passages in cell culture to isolate viral variants that cause only limited infection in humans. The virus is produced as purified calf lymph and given percutaneously with a bifurcated needle. This vaccine was used in the first successful worldwide efforts to eradicate a human virus, variola or smallpox. Routine universal vaccinia immunization was discontinued around 1980, following the declaration by WHO that variola (smallpox) was eradicated, but the vaccine is still available. The nonemergency use of vaccinia vaccine includes vaccination of laboratory and healthcare workers exposed occupationally to vaccinia virus, to recombinant vaccinia viruses, or other orthopoxviruses that can infect humans, such as monkeypox virus and cowpox virus. Because there are still laboratory stocks of variola in research use in several countries, including the U.S., the U.S. ACIP has developed recommendations for the use of vaccinia vaccine if variola virus were used as an agent of biological terrorism or if a smallpox outbreak occurred accidentally. Large-scale use in the military and consideration of use in medical first responders in the U.S. has been implemented in recent decades. A derivative of conventional vaccinia virus vaccine has been developed that has desirable properties. MVA virus is a highly attenuated strain of vaccinia virus isolated after more than 500 passages in chicken embryo fibroblasts, during which the virus lost about 10% of the vaccinia genome and the ability to replicate productively in human and other primate cells.

**Other Vaccines for Biodefense and Special Pathogens**

There are a number of limited-use vaccines, such as those for workers in high-containment facilities conducting research on highly pathogenic agents that are emerging infectious diseases or potential agents for use in bioterrorism or biowarfare. Typically, these vaccines are used only under Investigational New Drug status. Examples include vaccines for Eastern equine encephalitis (EEE) virus, Venezuelan equine encephalitis (VEE) virus, Rift Valley fever virus, botulinum toxin, and others.

**International Vaccines**

There are additional vaccines pertinent to exposures in other countries that are licensed in some areas, but not yet in the U.S.

**Dengue Virus Vaccine**

Dengue fever is another mosquito-borne flaviviral disease caused by four different viral serotypes and annually affecting about 400 million people worldwide. The disease can be a mild systemic febrile illness during primary infection but can cause severe dengue disease and death during a second infection with virus of a different serotype. It is thought that cross-reactive nonneutralizing antibodies induced by one infection enhance the disease caused by subsequent infection with a heterologous serotype virus. This antibody-dependent enhancement concern has been a significant barrier to vaccine development efforts. Nevertheless, much progress has been made recently in dengue vaccine development.

There is currently no dengue vaccine approved for use in the U.S.; however, CYD-TDV developed by Sanofi Pasteur is a recombinant tetravalent (four-serotype) live attenuated virus vaccine that was first licensed in Mexico in December 2015 for use in individuals 9–45 years of age living in endemic areas. It is given as a three-dose series on a 0-, 6-, and 12-month schedule. Additional dengue vaccine candidates are in clinical development.
Malaria Vaccine

The RTS,S vaccine is a recombinant protein-based malaria vaccine with AS01 adjuvant against Plasmodium falciparum that was developed by a large international public-private consortium and is the first malaria vaccine to complete efficacy trial testing with a positive review of the outcome. It is relevant for P. falciparum, which is common in sub-Saharan Africa, but does not protect against Plasmodium vivax malaria, which is more common in many countries outside Africa. The EMA issued a “European scientific opinion” on the vaccine, and WHO and its SAGE have advocated its use in large-scale implementation pilot tests in Africa.

BCG Vaccine

BCG vaccine is used to prevent severe disease due to Mycobacterium tuberculosis (TB). BCG vaccine is produced using a live attenuated bovine bacillus strain, Mycobacterium bovis, that has lost its ability to cause severe disease in humans. The vaccine typically is given as a single intradermal dose, often to infants near the time of birth. The efficacy of BCG vaccine against TB is uncertain in many settings, but the consensus is that the vaccine does protect against the most severe forms of disseminated TB, such as miliary disease and TB meningitis. The vaccine is a WHO essential medicine for endemic areas but is not used for universal vaccination in the U.S.

The Future of Vaccine Technology

Vaccination technology and improved methods to generate vaccines have led to the prevention of many infectious diseases. People no longer die at the high rates that prevailed before vaccines were developed. In the developing world, however, according to WHO reports, over 40% of deaths are due to infectious diseases, highlighting a continued need to improve existing vaccines, develop new vaccines, and improve delivery methods to increase efficacy. Viruses, bacteria, parasites, and antigens on cancerous cells are all future vaccine targets. New vaccines for pregnant mothers will be available to prevent diseases that can become chronic if the fetus becomes infected in utero, as is the case with malaria. Furthermore, an increasing elderly population will need access to better vaccines that can stimulate their aging immune systems, which are susceptible to infections like influenza and varicella viruses. Delivery methods are being explored to utilize nanoparticles and alternative adjuvants to improve vaccine immunogenicity so people will only need one vaccine dose rather than several. Needle-less delivery is already possible, as in the case of oral polio vaccine or via nasal sprays for influenza. Investigation continues on developing new edible vaccines using plants, microneedles, and needle-free dermal patches.

Most vaccines work through preventing disease due to acute infections; the challenge remains to develop vaccines against chronic viral infections where the host is immunosuppressed. These pathogens evade the immune system and persist in the host’s own cells. To overcome these chronic pathogens, vaccines need to elicit both antibody and T cell responses, where B cells can neutralize the pathogen and T cells can actively kill and destroy infected cells. Vaccines against HIV and hepatitis B viruses protect not only from viral infection but also from developing infection-associated cancers.

New vaccines for other viral pathogens that can cause further complications are needed. For example, infection with group A streptococcus can lead to rheumatic fever, Helicobacter pylori may result in stomach cancer, and chlamydia infection can cause blindness and infertility. Vaccines provide effective prophylaxis; however, the frontier in vaccine technology will involve vaccines as therapies for already-established disease. Vaccines can be utilized against pathogens that become chronic, as in shingles, and also in conditions of autoimmunity and cancer, where the immune response is dysregulated. In the case of cancer, vaccines can be utilized to augment immunity to tumors to prevent their growth and metastasis. In the case of autoimmunity, the goal of this “negative vaccination” is to use vaccines to dampen immune function to prevent self-tissue destruction (Nossal, 2011).

Vaccine Safety: Myths, Truths, and Consequences

Vaccine Adjuvants and Safety

Adjuvants are substances added to vaccines to enhance the magnitude, quality, and duration of the protective immune response. Adjuvants are useful in vaccines because they stimulate the innate immune system that subsequently activates a strong adaptive immune response to ensure immune protection. Because many modern vaccines do not contain live pathogens, they must include adjuvants to ensure vaccine efficacy. Adjuvants are particularly useful in subunit protein vaccines, which often are inadequately immunogenic without enhancement.

There is extensive experience in human vaccines with two adjuvants, aluminum and monophosphoryl lipid A. Aluminum, in the form of alum, has been used for nearly 90 years in vaccines; aluminum hydroxide [Al(OH)₃] and aluminum phosphate (AlPO₄) are currently used. Aluminum is used in many childhood vaccines in the U.S. targeted to diphtheria-tetanus-pertussis, Hib and pneumococcus, hepatitis A and B, and HPV. Monophosphoryl lipid A (isolated from bacteria) has been used in the HPV vaccine Cervarix since 2009. A new influenza vaccine licensed for the 2016–2017 season included the adjuvant MF59, an oil-in-water emulsion of squalene oil. Another new influenza vaccine that is targeted to influenza H5N1 contains a new adjuvant termed AS03 (an “adjuvant system” containing α-tocopherol and squalene in an oil-in-water emulsion) and was licensed for inclusion in the U.S. pandemic influenza vaccine stockpile. Live attenuated virus vaccines do not contain adjuvants; thus, adjuvant-free vaccines include those directed against measles, mumps, rubella, chickenpox, rotavirus, polio, and live attenuated seasonal influenza virus.

Vaccines Do Not Cause Autism

Autism spectrum disorder rates have increased in the U.S. and other parts of the world in parallel with expansion in the diagnostic criteria of autism that now include spectrum disorders with a broader array of symptoms (Hansen et al., 2015). The CDC found that 1 of 68 children in the U.S. has ASD. Patients with this disorder have development impairments that affect their communication, behavior, and social interactions. Even though some people have been concerned with a causal link between vaccines and autism, many large scientific studies have failed to detect any such link (Hviid et al., 2003; Madsen et al., 2002; Schechter and Grether, 2008; Taylor et al., 2014). The IOM (now termed the National Academy of Medicine) conducted thorough reviews and concluded that current childhood and adult vaccines are very safe. In 2014, a CDC study added to reports around the world that vaccines do not cause ASD. They concluded that the total amount of antigen received from vaccines did not differ between children with ASD and those without the disorder. Vaccination with the MMR vaccine also is not associated with development of ASD in children.

Preservatives, Including Thimerosal

Preservatives added to vaccine preparations are designed to kill or inhibit the growth of bacteria and fungi that could contaminate a vaccine vial. There are historical reports of severe adverse events or death due to bacterial contamination of multidose vials lacking preservative. The highest risk of contamination is probably due to repetitive puncture of a multidose vaccine vial that is stored over time. Therefore, The U.S. Code of Federal Regulations requires the addition of a preservative to multidose vials of vaccines. Preservatives eliminate or reduce contamination in this setting. Several preservatives have been incorporated into licensed vaccines, including 2-phenoxethanol, benzethonium chloride, phenol, and thimerosal.
Thimerosal, known to many by the trade name Merthiolate, has been one of the most commonly used preservatives; it is an organomercurial, an organic compound containing mercury. Thimerosal has been used safely since the early 20th century as a preservative in biologics, including many vaccines, and has a long history of use. Over time, concerns were raised about its safety because some organomercurials were increasingly associated with neurotoxicity, and children began receiving increasing numbers of licensed vaccines. The FDA chose to work with manufacturers toward reduction or elimination of thimerosal from childhood vaccines because of these theoretical concerns. As a result, thimerosal has been eliminated or reduced to trace amounts in nearly all childhood vaccines except some IVs.

In terms of toxicity from mercury, most of the data in the field pertains to methylmercury, whereas thimerosal is a derivative of ethylmercury, which is cleared more rapidly. Thimerosal does not have significant toxic effects at the concentrations used in vaccine formulations. However, questions were raised about the potential association of thimerosal-containing vaccines in children and the occurrence of neuromuscular disorders, especially autism. A rather sordid history of fraud, conflict of interest, and other irregularities has been revealed pertaining to the now-debunked association studies of thimerosal and autism; decades of studies have been conducted in safety reviews around this matter.

The National Vaccine Advisory Committee, ACIP of the CDC, and the IOM’s Immunization Safety Review Committee have all conducted extensive reviews of association studies, and the conclusion is that autism is not associated with the amount of thimerosal in childhood vaccines. In any event, recognizing public concern, between 2001 and 2003, thimerosal was eliminated from or reduced in childhood vaccines (except for flu) for children under 6 years old in hopes of encouraging childhood vaccination. The CDC has compiled a thorough review and list of articles relating to this issue (CDC, 2015).

**Adverse Events With Vaccines**

For injectable vaccines, common adverse effects include minor local reactions to vaccines at the injection site (pain, swelling, and redness). More widespread effects, termed systemic reactions, may include fever, rash, irritability, drowsiness, and other symptoms, depending on the vaccine. The profile of reactions seen in large-scale trials is carefully documented in package inserts. During vaccine candidate testing, any occurrence of serious adverse events (SAEs) are examined carefully. SAEs are events following vaccination that involve hospitalization, life-threatening events, death, disability, permanent damage, congenital anomaly/birth defect, or other conditions requiring medical intervention. Vaccines with clear association with SAEs are typically not licensed. In some cases, to increase the likelihood of detecting of rare SAEs, the FDA requires phase 4 studies (postmarketing surveillance) to follow the performance of vaccines as use expands beyond the size of the trials leading to licensure. The government also collects data after licensure through the vaccine adverse event reporting system (VAERS). Vaccines can be withdrawn from market if concerns arise. For example, licensure for use of the live oral rotavirus vaccine Rotashield, which was recommended for routine immunization of the U.S. infants in 1998, was withdrawn in 1999 when reports in VAERS suggested an association between the vaccine and intussusception, a form of bowel obstruction.

**Allergic Reactions**

Allergy to components of vaccine formulations also can cause reactions. Trace amounts of antibiotics like neomycin, used to ensure sterility in some vaccines (e.g., MMR, trivalent IPV, and varicella vaccine), may cause adverse reactions. A history of anaphylactic reaction (but not local reaction) to neomycin is a contraindication to future immunization with those vaccines. Persons with a history of egg allergy should not be given an influenza vaccine prepared in eggs. Gelatin, which is used as a stabilizer in some virus vaccines like varicella and MMR vaccines, may cause allergic reaction in some.

**Fainting**

Fainting, or syncope, also has been reported in people after vaccination. Fainting is more common in adolescents than in children or adults and thus is more common after vaccination with HPV, MCV4, and Tdap. Immediate fainting episodes following vaccination procedures is triggered by pain or anxiety, rather than the contents of the vaccines. While fainting is not serious, falling while fainting can cause injury, with head injuries the most serious. Clinicians can give patients drinks and snacks to prevent some fainting and can prevent falls by having patients lie down or sit during the procedure. Patients who faint after vaccination will recover after a few minutes, and clinicians should observe patients for at least 15 min after vaccination (a recommendation of the CDC).

**Febrile Seizure**

Fever of 102°F (38.9°C) or higher can cause children to experience febrile seizures, which are characterized by body spasms and jerky movements that may last for up to 2 min. About 5% of children will experience a febrile seizure in their lifetime, with most occurring at 14–18 months of age. Children experiencing simple febrile seizures recover quickly without long-term harm. These common seizures also are caused by febrile illnesses associated with viral infections, especially roseola, ear infections, and other common childhood illnesses. Current vaccines sometimes induce fevers, usually low grade in nature, but rarely result in febrile seizures. Although fever following vaccination with most vaccines rarely causes febrile seizure, there is a small increase in risk after MMR and MMRV vaccines. The CDC also has reported a small increase in febrile seizures after a child receives the IIV together with PCV13 vaccine or in combination with diphtheria, tetanus, or DTaP vaccines. The increase of febrile seizures when combining these vaccines is small, and the CDC does not recommend delivering them on separate days. Importantly, vaccine usage can help prevent febrile seizures by providing vaccinated children protection against measles, mumps, rubella, chickenpox, influenza, and pneumococcal infectious pathogens that may result in febrile seizures.

**Guillain-Barré Syndrome**

Guillain-Barré syndrome is a rare disease that affects the nervous system. Patients with GBS display muscle weakness and sometimes paralysis that results when their own immune system injures their neurons. GBS often occurs after an infection with bacteria or virus; most patients with GBS recover fully. However, some subjects can have permanent nerve damage. The incidence of GBS in the U.S. currently is about 3000–6000 cases per year; thus, it is rare in a population of about 350 million. GBS is more common in older adults, with people older than 50 years at greater risk. GBS may have several underlying causes, but scientists report that two-thirds of GBS cases occurred after patients were ill with gastroenteritis or respiratory tract infections. Infection with Campylobacter jejuni is the most common risk factor for the disease, but GBS also has been reported commonly after influenza virus, cytomegalovirus, or Epstein-Barr viral infection. GBS after vaccination is reported but rare.

An IOM study reported that widespread use of the 1976 swine influenza virus vaccine was associated with a small increase in risk for GBS, with an additional case of GBS per 100,000 people who were vaccinated, although later statistical review called this association into question. Current assessments are that the there is no significant risk of GBS after obtaining a seasonal influenza vaccine, or if there is an association, the risk is approximately one case per million vaccinated individuals, a low rate that is difficult to detect with certainty. Studies have shown that a person is more likely to get GBS after influenza infection than vaccination. Importantly, severe morbidity and mortality are a significant risk after influenza infection, and preventing complications and death can be achieved by getting vaccinated.

**Sudden Infant Death Syndrome**

Sudden infant death syndrome peaks when babies are between 2 and 4 months old, and infants are also given many vaccines during this period. The temporal overlap of peak SIDS incidence and the period of initiation of childhood vaccination series led to questions about any causal relationship between vaccines and SIDS. Numerous studies have failed to detect a
causative association for vaccines and SIDS (Silvers et al., 2001). The IOM 2003 report reviewed the relationship of SIDS and vaccines and concluded that vaccines do not cause SIDS. Infant death by SIDS has decreased dramatically due to the 1992 American Academy of Pediatrics recommendations to place infants on their backs to sleep and the 1994 National Institute of Child Health and Human Development campaign efforts.

**Safety of Multiple Vaccinations**

Children are exposed to a large number of bacteria and viruses in their environment through food, teething of objects, and exposure to pets and to other humans. The typical viral infection results in exposure of the immune system to a dozen or more antigens; some bacteria express hundreds of antigens during infection. Each recommended childhood vaccine protects against 1 to 69 antigens. When a child is given the full recommended vaccines on the 2014 schedule, they are exposed to up to 315 antigens by age 2, which provides them critical protection against pathogens in the environment (CDC, 2016). Vaccinating patients against multiple antigens has been shown to be safe when they are delivered in combination at the same time. This strategy is advantageous for patients, especially children, because they lack immunity to most vaccine preventable diseases, so receiving this protection during the relatively vulnerable period of early development is important. The patient also has fewer doctor visits with combination or multiple vaccinations, reducing cost in terms of money and time for parents and disruption for children. Numerous studies have shown that giving various vaccine combinations does not cause chronic disease. Furthermore, each time a combination vaccine or multiple vaccination schedule is licensed, that intervention already has been tested for safety and efficacy in combination with the vaccines previously recommended for that age group. The ACIP and the Academy of Pediatrics recommend receiving multiple vaccines at the same time (CDC, 2016).

**Vaccine Myths and Their Public Health Consequences**

The public health success of vaccines is demonstrated by the decreased rates of mortality and morbidity due to infectious diseases contracted in childhood and adulthood. A dramatic example of success is the worldwide eradication of smallpox, a pathogen responsible for epidemics that killed 300–500 million people in the 20th century and disfigured many survivors. In the 20th century, poliovirus and MeV also incapacitated and killed infected individuals, especially young children. New generations have never seen the debilitated effects of these infectious diseases, thanks to decades of successful public health vaccination strategies. Infectious diseases, however, continue to affect the lives of many people in the developing world who have less access to healthcare or are affected by wars or famine. Recently, preventable diseases are arising again in the developed world because of vaccine myths that have reduced vaccination rates in these countries.

One of these myths concerns autism. A study that has been retracted and discredited claimed there was a link between vaccination in children and autism (Wakefield et al., 1998). Despite major shortcomings and incorrect interpretations, this study changed public perceptions regarding vaccine safety, and its influence persists. Experimental studies in different parts of the world with large cohorts, statistical power, and rigor have found no evidence that vaccines cause autism (American Academy of Pediatrics, 2017; Madsen et al., 2002). Researchers have found that autism occurs in families, may have a genetic component, and may be affected by environmental triggers such as insecticides, certain drugs, and rubella virus. The exact causes of ASDs are unknown and continue to be investigated (Landrigan, 2010).

Nonetheless, the antivaccination movement has gained momentum, with celebrities, politicians, and social media continuing to propagate erroneous vaccine information and conspiracy theories. According to the CDC, vaccination rates have fallen in many parts of the U.S. In nine U.S. states, fewer than two-thirds of children ages 19 to 35 months have been vaccinated with the recommended seven-vaccination regimen. This dismissal of scientific evidence on vaccines can have deadly consequences. Infectious epidemics due to preventable agents like poliovirus and MeV can reemerge. Unvaccinated children will be more susceptible to infection, and many of them will not survive. Furthermore, unvaccinated subjects contribute to reducing the benefits of herd immunity that protects people who cannot be vaccinated for medical reasons, such as cancer, HIV infection, and other types of immunodeficiency.

Diseases due to pertussis, polio, measles, *H. influenzae*, and rubella virus once affected hundreds of thousands of people and killed thousands. Following the introduction of universal vaccinations, the rates of these diseases decreased to near-zero levels in the U.S. Some believe that because these diseases have been nearly eliminated in the U.S., vaccination is no longer needed. This thinking is incorrect. Vaccine-preventable diseases are communicable diseases, spreading from person to person, and the causative viruses and bacteria survive in nature. People, especially the unvaccinated, can be infected, and infected individuals will spread the disease to unvaccinated individuals. A greater fraction of vaccinated individuals in a population leads to fewer opportunities for the disease to spread (herd immunity).

Parental vaccine concerns should be taken seriously, and misconceptions should be thoroughly discussed by providers to ensure that patients have scientific information and are informed about the risks associated with failure to vaccinate. By providing parental education, pediatricians and other primary care medical providers can help reduce vaccine hesitancy.

**Licensure and Monitoring of Vaccines**

**Immune Correlates and Mechanisms**

During the process of vaccine development and testing, manufacturers seek to define laboratory tests and parameters that are associated with efficacy, which have been designated immune CoPs. First, it is important theoretically to understand some features of the biological mechanism of protection to optimize development and use of vaccines. At a practical level, identification of a correlate allows monitoring of the reproducibility of vaccines during repetitive manufacture, monitoring the expected impact of new combinations of vaccine antigens on immunogenicity of existing vaccines, and other critical issues.

Plotkin and others have developed terminology for principal types of correlates (Plotkin and Gilbert, 2012). A CoP is a marker of immune function that statistically correlates with protection. Such markers can be simply associated with protection (termed nCoP) or alternatively may be known to measure directly the immune effectors that mediate protection (mCoP). From a practical standpoint, either an nCoP or an mCoP can enable monitoring and prediction of effective vaccination.

The ideal CoP is one that is quantitative and derives from a reproducible laboratory test that has been validated under good laboratory practice conditions. The type of protection suggested for a particular correlate may vary because vaccines may be designed to prevent differing classes of infection, such as local versus systemic infection or severe disease versus any disease. Examples of quantitative CoPs in use include a threshold of 10 mIU/mL in serum of hepatitis B antibodies detected in a standardized ELISA (enzyme-linked immunosorbent assay), serum diphtheria toxin neutralization concentration of 0.01 to 0.1 IU/mL, a serum virus neutralization dilution titer of 1/5 for yellow fever virus, or a 1/40 dilution of serum in influenza hemagglutination inhibition titer.

**Regulatory and Advisory Bodies**

The Center for Biologics Evaluation and Research (CBER) of the FDA regulates vaccine products in the U.S., with recommendations from its Vaccines and Related Biological Products Advisory Committee. The EMA regulates in Europe. Manufacturers conduct phase I (safety and immunogenicity studies) in a small number of closely monitored subjects; phase 2 studies (dose-ranging studies) typically in several hundred subjects; and then phase 3 trials (efficacy studies) typically in thousands of subjects. If successful, the sponsor submits a Biologics License Application (BLA) to the FDA, which may lead to licensure. Licensure allows use, but decisions on whether vaccines are recommended for specific populations.
or for universal use are made by additional advisory bodies. The CDC hosts the ACIP, a committee of public health and medical experts, which makes recommendations for use of vaccines in the U.S. Various professional medical societies also publish recommendations, for instance, the American Academy of Pediatrics publishes the AAP Red Book, or "Report of the Committee on Infectious Diseases of the American Academy of Pediatrics," which contains vaccine recommendations. Finally, third-party payers, such as insurance companies, affect usage through reimbursement policies; thus, issues of cost, benefit, and profitability become considerations, as examined in Chapter 1.

Bibliography

Membrane lipids supply the substrate for the synthesis of eicosanoids and platelet-activating factor (PAF). Arachidonic acid (AA) metabolites, including PGs, PGI₂, TXA₂, LTs, and epoxysugene products of CYPs, collectively the eicosanoids, are not stored but are produced by most cells when a variety of physical, chemical, and hormonal stimuli activate acyl hydrolases that make arachidonate available. Membrane glycerophosphocholine derivatives can be modified enzymatically to produce PAF. PAF is formed by a smaller number of cell types, principally leukocytes, platelets, and endothelial cells. Eicosanoids and PAF lipids function as signaling molecules in many biological processes, including the regulation of vascular tone, renal function, hemostasis, parturition, GI mucosal integrity, and stem cell function. They are also important mediators of innate immunity and inflammation. Several classes of drugs, most notably NSAIDs (see Chapter 38), including aspirin, owe their principal therapeutic effects—relief of inflammatory pain and antipyresis—to blockade of PG formation.

**Eicosanoids**

Eicosanoids, from the Greek eikosi ("twenty") are formed from precursor essential fatty acids that contain 20 carbons and 3, 4, or 5 double bonds: 8,11,14-eicosatrienoic acid (dihomo-γ-linolenic acid), 5,8,11,14-eicosatetraenoic acid (AA; Figure 37–1), and EPA. AA is the most abundant precursor, derived from the dietary omega-6 fatty acid, linoleic acid (9,12-octadecadienoic acid), or ingested directly as a dietary precursor essential fatty acids that contain 20 carbons and 3, 4, or 5 double bonds: 8,11,14-eicosatrienoic acid (dihomo-γ-linolenic acid), 5,8,11,14-eicosatetraenoic acid (AA; Figure 37–1), and EPA. AA is the most abundant precursor, derived from the dietary omega-6 fatty acid, linoleic acid (9,12-octadecadienoic acid), or ingested directly as a dietary constituent. EPA is a major constituent of oils from fatty fish such as salmon.

**History**

In 1930, American gynecologists Kurzrok and Lieb observed that strips of uterine myometrium relax or contract when exposed to semen. Subsequently, Goldblatt in England and von Euler in Sweden reported independently on smooth muscle contracting and vasodilator activity in seminal fluid and accessory reproductive glands. In 1935, von Euler identified the active material as a lipid-soluble acid, which he named prostaglandin. Samuelsson, Bergström, and their colleagues elucidated the structures of PGE, and PGF, in 1962. In 1964, Bergström and coworkers and van Dorp and associates independently achieved biosynthesis of PGE1 from AA. Discovery of TXA2, PGI2, and the LTs followed. Vane, Smith, and Willis in 1971 reported that aspirin and NSAIDs act by inhibiting PG biosynthesis. This remarkable period of discovery linked the Nobel Prize of von Euler in 1970 to that of Bergström, Samuelsson, and Vane in 1982.

**Products of Cyclooxygenases (Prostaglandin G/H Synthases)**

Prostaglandin endoperoxide G/H synthase is called cyclooxygenase or COX colloquially. Products of this pathway are PGs, PGI₂, and TXA₂, collectively termed prostanooids. The pathway is described by Figure 37–1 and its legend.

Prostanooids are distinguished by substitutions on their cyclopentane rings the number of double bonds in their side chains, as indicated by numerical subscripts (dihomo-γ-linolenic acid is the precursor of series, AA for series, and EPA for series). Prostanooids derived from AA carry the subscript 2 and are the major series in mammals. There are two distinct COX isoforms, COX-1 and COX-2 (Rouzer and Marnett, 2009; Smith et al., 2011). COX-1, expressed constitutively in most cells, is the dominant source of prostanooids for housekeeping functions, such as cytoprotection of the gastric epithelium (see Chapter 49). COX-2, in contrast, is upregulated by cytokines, shear stress, and growth factors and is the principal source of prostanooid formation in inflammation and cancer. However, this distinction is not absolute; both enzymes may contribute to the generation of autoregulatory and homeostatic prostanooids during physiologic and pathophysiologic processes.

With 61% amino acid identity, COX-1 and COX-2 have remarkably similar crystal structures. Both isoforms are expressed as dimers homotypically inserted into the endoplasmic reticular membrane. Through sequential COX and POX activity, both COXs convert AA to two unstable intermediates that are then converted to the prostanooids.

**Biosynthesis**

Biosynthesis of eicosanoids is limited by the availability of AA and depends primarily on the release of esterified AA from membrane phospholipids or other complex lipids by acyl hydrolases, notably PLA₂. Once liberated, AA is metabolized rapidly to oxygenated products by COXs, LOXs, and CYPs (Figure 37–1).

Chemical and physical stimuli activate the Ca²⁺–dependent translocation of group IV, cytosolic phospholipase A₂ (cPLA₂) to the membrane, where it hydrolyzes the sn-2 ester bond of membrane phosphatidylcholine and phosphatidylethanolamine, releasing AA. Multiple additional PLA₂ isoforms (secretory [s] and Ca²⁺–independent [i] forms) have been characterized. Under basal conditions, AA liberated by iPLA₂ is reincorporated into cell membranes. During stimulation, cPLA₂ dominates the acute release of AA, while an inducible sPLA₂ contributes to AA release under conditions of sustained or intense stimulation. SPLA₂ contributes to platelet microparticle generation of eicosanoids that then direct microparticle internalization by neutrophils driving inflammation (Duchez et al., 2015).

**Platelet-Activating Factor**

Chemical and physical stimuli activate the Ca²⁺–dependent translocation of group IV, cytosolic phospholipase A₂ (cPLA₂) to the membrane, where it hydrolyzes the sn-2 ester bond of membrane phosphatidylcholine and phosphatidylethanolamine, releasing AA. Multiple additional PLA₂ isoforms (secretory [s] and Ca²⁺–independent [i] forms) have been characterized. Under basal conditions, AA liberated by iPLA₂ is reincorporated into cell membranes. During stimulation, cPLA₂ dominates the acute release of AA, while an inducible sPLA₂ contributes to AA release under conditions of sustained or intense stimulation. SPLA₂ contributes to platelet microparticle generation of eicosanoids that then direct microparticle internalization by neutrophils driving inflammation (Duchez et al., 2015).
CHAPTER 37

LIPID-DERIVED AUTACOIDS: EICOSANOIDS AND PLATELET-ACTIVATING FACTOR

Abbreviations

AA: arachidonic acid
ACTH: corticotropin (formerly adrenocorticotropic hormone)
BLT1/2: LTB4 receptors
cAMP: cyclic adenosine monophosphate
COX: cyclooxygenase
CYP: cytochrome P450
CysLT: cysteinyl leukotriene
CysLT1/2: CysLT receptors
DP: a member of the fMLP-receptor superfamily, CRTH2
DP: PGD2 receptor
EDHF: endothelium-derived hyperpolarizing factor
EET: epoxyeicosatrienoic acid
EP: PGE2 receptor
EPA: 5,8,11,14,17-eicosapentaenoic acid
FLAP: 5-LOX–activating protein
FP: PGF2α receptor
fMLP: formyl-methionyl-leucyl-phenylalanine
GPCR: G protein–coupled receptor
HETE: hydroxyeicosatetraenoic acid
HPETE: hydroxyprostyeicosatetraenoic acid
IL: interleukin
IP: independent PL A2
iPLA2: independent PLA2
iPr: isoprostane
LOX: lipoxygenase
LT: leukotriene
LX: lipoxin, e.g., LXA4, LXB4
LX*: lipoxin*, e.g., LXA4, LXB4
NSAID: nonsteroidal anti-inflammatory drug
PAF: platelet-activating factor
PAF-AH: PAF acetylhydrolase
PG: prostaglandin
PGDH: PG 15-0H dehydrogenase
PGI2: prostacyclin
PL*: phospholipase*, e.g., PLA, PLC
PMN: polymorphonuclear leukocyte
POX: peroxidase
TNF: tumor necrosis factor
TP: TXA2 receptor
TXA: thromboxane A

There are five active human LOXs—5(S)-LOX, 12(S)-LOX, 12(R)-LOX, 15(S)-LOX-1, and 15(S)-LOX-2—classified according to the site of hydroperoxy group insertion. Their expression is frequently cell specific: platelets have only 12(S)-LOX, whereas leukocytes contain both S(S)- and 12(S)-LOX (Figure 37–2). 12(R)-LOX is restricted in expression mostly to the skin. The epidermal LOXs, which constitute a distinct LOX subgroup, also include 15-LOX-2 and eLOX-3, the most recently identified family member. eLOX-3 has been reported to metabolize further 12(R)-HETE, the product of 12(R)-LOX, to a specific epoxyalcohol product.

The 5-LOX pathway leads to the synthesis of the LTs. When eosinophils, mast cells, PMNs, or monocytes are activated, 5-LOX translocates to the nuclear membrane and associates with FLAP, an integral membrane protein that facilitates AA to 5-LOX interaction (Evans et al., 2008). Drugs that inhibit FLAP block LT production. A two-step reaction is catalyzed by 5-LOX: oxygenation of AA to form 5-HPETE followed by dehydration to an unstable epoxide, LTA4, which is transformed by distinct enzymes to LTB4, or LTC4. Extracellular metabolism of the peptide moiety of LTC4 generates LTD4 and LTE4 (Peters-Golden and Henderson, 2007). Collectively, LTC4, LTD4, and LTE4 are the CysLTs. LTD4 and LTE4 are actively transported out of the cell. LTA4, the primary product of the 5-LOX pathway, is metabolized by 12-LOX to form LXA4 and LXRA. These mediators also can arise through 5-LOX metabolism of 15-HETE.

**Products of CYPs**

The CYP epoxygenases, primarily CYP2C and CYP2J, metabolize AA to EETs (Fleming, 2014). In endothelial cells, EETs function as EDHFs, particularly in the coronary circulation. EET biosynthesis can be altered by pharmacological, nutritional, and genetic factors that affect CYP expression.

**Other Pathways**

The isoeicosanoids, a family of eicosanoid isomers, are generated by non-enzymatic free radical catalyzed oxidation of AA. Unlike PGs, these compounds are initially formed esterified in phospholipids and released by PLA2; the isoeicosanoids then circulate and are metabolized and excreted into urine. Their production is not inhibited in vivo by inhibitors of COX-1 or COX-2, but their formation is suppressed by antioxidants. Isoprostanes correlate with cardiovascular risk factors, and increased levels are found in a large number of clinical conditions (Milne et al., 2015). Their relevance as biologically active mediators remains unclear. A series of compounds, Lxs, maresins, resolvins, when synthesized and administered to certain models of inflammation, hasten its resolution. It remains to be established whether the endogenous compounds are formed in quantities sufficient to exert this effect in vivo (Skarke et al., 2015).

**Inhibitors of Eicosanoid Biosynthesis**

Inhibition of PLA2 decreases the release of the precursor fatty acid and the synthesis of all its metabolites. PLA2 may be inhibited by drugs that reduce the availability of Ca2+. Glucocorticoids inhibit PLA2, indirectly by inducing the synthesis of a group of proteins termed annexins that modulate PLA2 activity. Glucocorticoids also downregulate induced expression of COX-2 but not of COX-1 (see Chapter 46). Aspirin and NSAIDs inhibit the COX, but not the POX, moiety of both COX enzymes and thus the formation of downstream prostanoids. These drugs do not inhibit LOXs and may cause increased formation of LTs by shunting of substrate to the LOX pathway. Dual inhibitors of COX and 5-LOX have proven effective in some models of inflammation and tissue injury (Minutoli et al., 2015; Oak et al., 2014). LTs may contribute to the GI side effects associated with NSAIDs (Janusz et al., 1998; Xu et al., 2009).

Differences in the sensitivity of COX-1 and COX-2 to inhibition by certain anti-inflammatory drugs led to the development of selective inhibitors of COX-2, including the coxibs (Grosser et al., 2010) (see Chapter 38). These drugs were hypothesized to offer therapeutic advantages over older NSAIDs (many of which are nonselective COX inhibitors) because COX-2 was thought to be the predominant source of PGs in inflammation, whereas COX-1 is the major source by syntheses, expressed in a relatively cell-specific fashion. For example, COX-2–derived TXA2 is the dominant product in platelets, whereas COX-2–derived PGE2 and TXA2 dominate in activated macrophages. Prostanoids are released from cells by diffusion, although transport may be facilitated through the multidrug resistance-associated protein (MRP) transporter (Schuster, 2002).

**Lipoxygenase Products**

Major products of the LOX pathways are hydroxy fatty acid derivatives known as HETEs, LTs, and Lxs (Figure 37–2) (Haegeström and Funk, 2011; Powell and Rokach, 2015). LTs play a major role in the development and persistence of the inflammatory response.

The LOXs are a family of enzymes containing nonheme iron; LOXs catalyze the oxygenation of polyenic fatty acids to corresponding lipid hydroperoxides. The enzymes require a fatty acid substrate with two cis double bonds separated by a methylene group. AA, which contains several double bonds in this configuration, is metabolized to HPETEs, which vary in the site of insertion of the hydroperoxy group. HPETEs are converted to their corresponding HETEs either nonenzymatically or by a POX.
Eventually prove to be useful in the prevention of cardiovascular disease. Golden and Henderson, 2007; thus, inhibition of LT biosynthesis may be linked to asthma, studies have demonstrated an association of these polymorphisms in the genes encoding 5-LOX or FLAP have yet to be confirmed. Aspirin and nonselective NSAIDs are nonselective inhibitors of COX-1 and COX-2 but do not affect LOX activity. See the text and the Abbreviations list for further definitions.

The lung, kidney, and liver play prominent roles in the enzymatically catalyzed reactions. Metabolic clearance requires an energy-dependent cellular uptake PG transporter and possibly other transporters (Schuster et al., 2002). The initial step is the oxidation of the 15-OH group to the corresponding ketone by PGDH. PGI2 and TxA2, however, undergo spontaneous hydrolysis as a first degradative step. LTC4 degradation also occurs in the lungs, kidney, and liver but may also occur in LTC4 via CYP4F enzymes. Inactivation of 15-hydroxyprostaglandin dehydrogenase, which elevates the capacity of tissues to form PGE2, enhances tissue regeneration after hematopoietic stem cell transplantation and after hemihepatectomy (Zhang et al., 2015).

Pharmacological Properties

Eicosanoid Degradation

Most eicosanoids are efficiently and rapidly inactivated (Figure 37–3). The enzymatic catalytic reactions are of two types:

- a rapid initial step, catalyzed by widely distributed PG-specific enzymes, wherein PGs lose most of their biological activity; and
- a second step in which these metabolites are oxidized, probably by enzymes identical to those responsible for the β and ω oxidation of fatty acids.

The lung, kidney, and liver play prominent roles in the enzymatically catalyzed reactions. Metabolic clearance requires an energy-dependent cellular uptake PG transporter and possibly other transporters (Schuster et al., 2002). The initial step is the oxidation of the 15-OH group to the corresponding ketone by PGDH. PGI2 and TxA2, however, undergo spontaneous hydrolysis as a first degradative step. LTC4 degradation also occurs in the lungs, kidney, and liver but may also occur in LTC4 via CYP4F enzymes. Inactivation of 15-hydroxyprostaglandin dehydrogenase, which elevates the capacity of tissues to form PGE2, enhances tissue regeneration after hematopoietic stem cell transplantation and after hemihepatectomy (Zhang et al., 2015).

Pharmacological Properties

The eicosanoids function through activation of specific GPCRs (Table 37–1) that couple to intracellular second-messenger systems to modulate cellular activity (Figure 37–4).

Figure 37–2 Lipoxygenase pathways of AA metabolism. FLAP presents AA to 5-LOX, leading to the generation of the LTs and CysLTs. LXs (boxed) are products of cellular interaction via a 5-LOX–12-LOX pathway or via a 15-LOX–5-LOX pathway. Biological effects are transduced via membrane-bound receptors (blue boxes). While its biological relevance remains controversial, LXA4 can activate a GPCR also activated by Annexin A1 and by the formyl peptide. This GPCR is termed the AnxA1-Formyl peptide receptor 2/ALX receptor (AnxA1-FPR2/ALX) to reflect the range of its putative ligands. Zileuton inhibits 5-LOX but not the COX pathways (expanded in Figure 37–1). CysLT antagonists prevent activation of the CysLT1 receptor. See the text and the Abbreviations list for further definitions.

</table>

This table lists the major classes of eicosanoid receptors and their signaling characteristics. Splice variants for EP₃, TP, and FP are indicated.

Prostaglandin Receptors
The PGs activate membrane receptors locally near their sites of formation. Eicosanoid receptors interact with Gₛ, Gᵢ, and Gₚ to modulate the activities of adenylyl cyclase and PLC (see Chapter 3). Single-gene products have been identified for the receptors for PGI₂ (the IP), PGF₂α (the FP), and TxA₂ (the TP). Four distinct PGE₂ receptors (EP₁–EP₄) and two PGD₂ receptors (DP₁ and DP₂—also known as CRTH₁) have been cloned. Additional isoforms of the TP (α and β), FP (A and B), and EP₃ (I–VI, e, f) receptors can arise through differential messenger RNA splicing (Smyth et al., 2009; Woodward et al., 2011). The prostanoid receptors appear to derive from an ancestral EP receptor and share high homology. Phylogenetic comparison of this receptor family reveals three subclusters (Figure 37–4):

- the relaxant receptors EP₂, EP₄, IP, and DP₁, which increase cellular cyclic AMP generation;
- the contractile receptors EP₁, FP, and TP, which increase cytosolic levels of Ca²⁺; and
- EP₃, which can couple to both elevation of cytosolic [Ca²⁺] and inhibition of adenylyl cyclase.

The DP₁ receptor is an exception and is unrelated to the other prostanoid receptors; rather, it is a member of the FMLP receptor superfamily.

Leukotriene Receptors
Two receptors exist for both LTB₄ (BLT₁ and BLT₂) and CysLT₁ and CysLT₂ (Bück et al., 2011, 2014). The FMLP-2 receptor also binds LXA₄, but the functional importance of this ligand in vivo remains controversial. All are GPCRs and couple with Gₛ and other G proteins, depending on the cellular context. BLT₁ is expressed predominantly in leukocytes, thymus, and spleen, whereas BLT₂, the low-affinity receptor for LTB₄, is found in spleen, leukocytes, ovary, liver, and intestine. CysLT₁ binds LTD₄ with higher affinity than LTC₄, while CysLT₂ shows equal affinity for both LTs. Both receptors bind LTE₄ with low affinity. Activation of Gₛ leading to mobilization of intracellular Ca²⁺ is the primary signaling pathway reported. Studies also have placed Gᵢ downstream of CysLT₂. CysLT₁ is expressed in lung and intestinal smooth muscle, spleen, and peripheral blood leukocytes, whereas CysLT₂ is found in heart, spleen, peripheral blood leukocytes, adrenal medulla, and brain.

Other Agents
Other AA-derived products (e.g., isoprostanes, EETs) have potent biological activities, and there is evidence for distinct receptors for some of these substances. An orphan receptor, GPR31, has been identified as a receptor for 12(S)-HETE (Powell and Rokach, 2015). Specific receptors for the HETEs and EETs have been proposed, and evidence that the orphan receptor GPR75 functions as a receptor for 20-HETE has recently been provided (Garcia et al., 2017).

Physiological Actions and Pharmacological Effects
The widespread biosynthesis and myriad pharmacological actions of eicosanoids are reflected in their complex physiology and pathophysiology. Knowledge of the distribution of the major eicosanoid receptors helps to put the complexity into perspective (Figure 37–1). The development of mice with targeted disruptions of genes regulating eicosanoid biosynthesis
Cardiovascular System

Because of their short t₁/₂, prostanooids act locally and generally are considered not to affect systemic vascular tone directly. They may modulate vascular tone locally at their sites of biosynthesis or through renal or other indirect effects. PGI₂, the major arachidonate metabolite released from the vascular endothelium, is derived primarily from COX-2 in humans. PGI₂ generation and release is regulated by shear stress and by both vasoconstrictor and vasodilator autacoids. In most vascular beds, PGE₂, PGI₂, and PGD₂ elicit vasodilation and a drop in blood pressure; physiologically, these responses are quite local because endogenous prostanooids are paracrine mediators that do not circulate (Smyth et al., 2009). Responses to these agents are quite local because endogenous prostanooids are paracrine mediators that do not circulate (Smyth et al., 2009).

Prostaglandin E₃ can also cause vasoconstriction through activation of EP₁ and EP₄. Infusion of PGD₂ in humans results in flushing, nasal stuffiness, and hypotension. Local subcutaneous release of PGD₂ contributes to dilation of the vasculature in the skin, which causes facial flushing associated with niacin treatment in humans. Subsequent formation of F-ring metabolites from PGD₂ may result in hypertension. Local subcutaneous release of PGD₂ contributes to dilation of the vasculature in the skin, which causes facial flushing associated with niacin treatment in humans. Subsequent formation of F-ring metabolites from PGD₂ may result in hypertension.

Cyclooxygenase 2–derived PGE₂, acting via the EP₂, maintains the ductus arteriosus patent until birth, when reduced PGE₂ levels (a consequence of increased PGE₂ metabolism) permit closure. The traditional NSAIDs induce closure of a patent ductus in neonates (see Chapter 38). Contrary to expectation, animals lacking the EP₂ die with a patent ductus during the perinatal period (Table 37–1) because the mechanism for control of the ductus in utero, and its remodeling at birth, is absent.

Infusion of PGs of the E and F series generally increases cardiac output. Weak, direct inotropic effects have been noted in various isolated preparations. In the intact animal, however, increased force of contraction and increased heart rate are, in large measure, a reflex consequence of a fall in total peripheral resistance. PGI₄ and PGE₂, acting on the IP or the EP₂, respectively, protect against oxidative injury in cardiac tissue.

Studies suggest a role for COX-2 in cardiac function. PGI₁ and PGE₂, acting on the IP or the EP₂, respectively, protect against oxidative injury in cardiac tissue. IP deletion augments myocardial ischemia/reperfusion injury, and both mPGE synthase-1 (mPGES-1) deletion and cardiomyocyte-specific deletion of the EP₂ exacerbate the decline in cardiac function after experimental myocardial infarction. COX 2–derived TxA₂ contributed to oxidant stress, isoprostane generation, and activation of the TP, and also possibly the FP, to increase cardiomyocyte apoptosis and fibrosis in a model of heart failure. Selective deletion of COX-2 in cardiomyocytes results in mild heart failure and a predisposition to arrhythmogenesis (Wang et al., 2009).

Leukotriene C₄ and LTD₄ can constric or relax isolated vascular smooth muscle preparations, depending on the concentrations used and the vascular bed (Bäck et al., 2011). Although LTC₄ and LTD₄ have little effect on most large arteries or veins, nanomolar concentrations of these agents contract coronary arteries and distal segments of the pulmonary artery. The renal vasculature is resistant to this constrictor action, but the mesenteric vasculature is not. LTC₄ and LTD₄ act in the microvasculature to increase permeability of postcapillary venules; they are about 1000-fold...
more potent than histamine in this regard. At higher concentrations, LTC4 and LTD4 can constrict arterioles and reduce exudation of plasma. There is evidence for a role of the LTs in cardiovascular disease (Peters-Golden and Henderson, 2007). Human genetic studies have demonstrated a link between cardiovascular disease and polymorphisms in the LT biosynthetic enzymes and FLAP.

The EETs cause vasodilation in a number of vascular beds by activating the large conductance Ca2+-activated K+ channels of smooth muscle cells, thereby hyperpolarizing the smooth muscle and causing relaxation. EETs likely also function as EDHFs, particularly in the coronary circulation. Endogenous biosynthesis of EETs is increased in human syndromes of hypertension.

Platelets
Platelet aggregation leads to activation of membrane phospholipases, with the release of AA and consequent eicosanoid biosynthesis. In human platelets, TXA2 and 12-HETE are the two major eicosanoids formed, although eicosanoids from other sources (e.g., PGI2 derived from vascular endothelium) also affect platelet function. Mature platelets express only COX-1. TXA2, the major product of COX-1 in platelets, induces platelet aggregation and amplifies the signal for other, more potent platelet agonists, such as thrombin and ADP. The importance of the TXA2 pathway is evident from the efficacy of platelet COX-1 inhibition with low-dose aspirin in the secondary prevention of myocardial infarction and ischemic stroke. The total biosynthesis of TXA2, as determined by excretion of its urinary metabolites, is augmented in clinical syndromes of platelet activation, including unstable angina, myocardial infarction, and stroke. Deletion of the TP in the mouse prolongs bleeding time, renders platelets unresponsive to TP agonists, and blunts the response to vasopressors and the proliferative response to vascular injury (Smyth et al., 2009). TXA2 induces platelet shape change, through Gq/G11-mediated Rho/Rho kinase–dependent regulation of myosin light-chain phosphorylation, and aggregation through Gq-dependent activation of PKC. The actions of TXA2 on platelets are restrained by its short t1/2 (~30 sec), by rapid TP desensitization, and by endogenous inhibitors of platelet function, including NO and PGI2.

Low concentrations of PGE2, via the EP2, enhance platelet aggregation. In contrast, higher concentrations of PGE2, acting via the IP or possibly EP2, or EP3, inhibit platelet aggregation. Both PGI2 and PGD2 inhibit the aggregation of platelets. PGI2 limits platelet activation by TXA2, and dis-aggregates preformed platelet clumps. The increased incidence of myocardial infarction and stroke in patients receiving selective inhibitors of COX-2, explained by inhibition of COX-2–dependent PGI2 formation, supports this concept (Grosser et al., 2010).

Inflammation and Immunity
Eicosanoids play a major role in inflammatory and immune responses. LTs generally are pro-inflammatory and interact with PGs to promote and sustain inflammation (Ricciotti and FitzGerald, 2011), although there are some exceptions, such as the inhibitory actions of PGE2 on mast cell activation. PGs and LXs and related compounds may also contribute to the resolution of inflammation (Buckley et al., 2014). COX-2 is the major source of prostanoids formed during and after an inflammatory response.

Prostaglandin E2, and PGI2, are the predominant pro-inflammatory prostanoids as a result of increased vascular permeability and blood flow in the inflamed region. TXA2 can increase platelet-leukocyte interaction. PGD2 may contribute to the resolution of inflammation. Lymphocytes have a minimal capacity to form PGs, yet they are a primary target of their action. PGs generally inhibit lymphocyte function and proliferation, suppressing the immune response. PGE2 depresses the humoral antibody response by inhibiting the differentiation of B lymphocytes into antibody-secreting plasma cells. PGE2 acts on T lymphocytes to inhibit mitogen-stimulated proliferation and lymphokine release by sensitized cells. PGE2 and TXA2, also may play a role in T-lymphocyte development by regulating apoptosis of immature thymocytes. PGE2, acting via EP2 and EP4, has been shown to interact with the programmed cell death ligand to restrain cytotoxic T-cell function and survival during chronic infection in mice (Chen et al., 2015). The COX-2/mPGES-1/PGE2 pathway can regulate PD-L1 expression in tumor infiltrating myeloid cells (Prima et al. 2017). Given the efficacy of blockade of this pathway in a range of cancers, the possibility that blockade of PGE2 synthesis or action might augment this effect has been suggested. PGD2 is a potent leukocyte chemotactant, primarily through the DP2.

The LTs are potent mediators of inflammation. Deletion of either 5-LOX or FLAP reduces inflammatory responses in model systems. LTs are potent chemotactic agents for neutrophils, T lymphocytes, eosinophils, monocytes, dendritic cells, and possibly also mast cells (Bäck et al., 2011). LTB4 stimulates the aggregation of eosinophils and promotes degranulation and the generation of superoxide. LTB4 promotes adhesion of neutrophils to vascular endothelial cells and their transendothelial migration and stimulates synthesis of pro-inflammatory cytokines from macrophages and lymphocytes.

The CysLTs are chemotaxins for eosinophils and monocytes. They also induce cytokine generation in eosinophils, mast cells, and dendritic cells. At higher concentrations, these LTs also promote eosinophil adherence, degranulation, cytokine or chemokine release, and oxygen radical formation. In addition, CysLTs contribute to inflammation by increasing endothelial permeability; thus promoting migration of inflammatory cells to the site of inflammation.

Bronchial and Tracheal Muscle
A complex mixture of autacoids is released when sensitized lung tissue is challenged by the appropriate antigen, including COX-derived bronchodilator and bronchoconstrictor substances. Amongst these, TXA2, PGE2 and PGD2 contract, and PGE2 and PGD2 relax, bronchial and tracheal muscle. PGI2 causes bronchodilation in most species; human bronchial tissue is particularly sensitive. PGI2 antagonizes bronchoconstriction induced by other agents. PGD2 appears to be the primary bronchoconstrictor prostanoid of relevance in humans. Polymorphisms in the genes for PGI2 synthase and the TP have been associated with asthma in humans.

Roughly 10% of people given aspirin or NSAIDs develop bronchospasm. This appears attributable to a shift in AA metabolism to LT formation. This substrate diversion appears to involve COX-1, not COX-2. CysLTs are bronchoconstrictors that act principally on smooth muscle in the Airways and are a thousand times more potent than histamine. They also stimulate bronchial mucus secretion and cause mucosal edema.

The CysLTs probably dominate during allergic constriction of the airway. Deficiency of 5-LOX leads to reduced influx of eosinophils in Airways and attenuates bronchoconstriction. Furthermore, unlike COX inhibitors and histaminergic antagonists, CysLT receptor antagonists and 5-LOX inhibitors are effective in the treatment of human asthma (see Inhibitors of Eicosanoid Biosynthesis). The relatively slow LT metabolism in lung contributes to the long-lasting bronchoconstriction that follows challenge with antigen and may be a factor in the high bronchial tone that is observed in asthmatic patients in periods between acute attacks (see Chapter 40).

GI Smooth Muscle
Prostaglandin E2 and PGF2a stimulate contraction of the main longitudinal muscle from stomach to colon. PG endoperoxides, TXA2, and PGI2, also produce contraction but are less active. Circular muscle generally relaxes in response to PGE2, and contracts in response to PGF2a. The LTs have potent contractile effects. PGs reduce transit time in the small intestine and colon. Diarrhea, cramps, and reflux of bile have been noted in response to oral PGE2. PGFs and PGEs stimulate the movement of water and electrolytes into the intestinal lumen. Such effects may underlie the watery diarrhea that follows their oral or parenteral administration. PGE2 appears to contribute to the water and electrolyte loss in cholera, a disease that is somewhat responsive to therapy with NSAIDs.

GI Secretion
In the stomach, PGE2 and PGI2 contribute to increased mucus secretion (cytoprotection), reduced acid secretion, and reduced pepsin content. PGs and its analogues also inhibit gastric damage caused by a variety of ulcerogenic agents and promote healing of duodenal and gastric ulcers (see Chapter 49). Although COX-1 may be the dominant source of such
cytoprotective PGs under physiological conditions, COX-2 predominates during ulcer healing. Selective inhibitors of COX-2 and deletion of the enzyme delay ulcer healing in rodents, but the impact of COX-2 inhibitors in humans is unclear. CysLTs, by constricting gastric blood vessels and enhancing production of pro-inflammatory cytokines, may contribute to the gastric damage.

**Uterus**

Strips of nonpregnant human uterus are contracted by PGF_2α_ and TxA_2_ but are relaxed by PGs. Sensitivity to the contractile response is most prominent before menstruation, whereas relaxation is greatest at midcycle. PGE_2_, together with oxytocin, is essential for the onset of parturition. PGI_2_, and high concentrations of PGE, produce relaxation. The intravenous infusion of low concentrations of PGE_2_ or PGF_2α_ to pregnant women produces a dose-dependent increase in uterine tone and in the frequency and intensity of rhythmic uterine contractions. PGEs and PGFs are used to terminate pregnancy. Uterine responsiveness to PGs increases as pregnancy progresses but remains smaller than the response to oxytocin.

**Kidney**

Cyclooxygenase–2–derived PGE_2_ and PGI_2_ increase medullary blood flow, resulting in pressure diuresis, and inhibit tubular sodium reabsorption (Hao and Breyer, 2007). Expression of medullary COX-2 is increased during high salt intake. COX-1–derived products promote salt excretion in the collecting ducts. Cortical COX–2–derived PGE_2_ and PGI_2_ increase renal blood flow and glomerular filtration through their local vasodilating effects and as part of the tubuloglomerular feedback mechanism that controls renin release. Expression of COX-2 in macula densa cells increases in conditions of low distal tubular flow during low dietary salt intake or volume depletion. COX–2–derived PGE_2_ and also possibly PGI_2_ results in increased renin release, leading to sodium retention and elevated blood pressure. TxA_2_ generated at low levels in the normal kidney, has potent vasoconstrictor effects that reduce renal blood flow and glomerular filtration rate. Infusion of PGE_2_ causes both natriuresis and diuresis. Conversely, PGE_2_ may activate the renin–angiotensin system, contributing to elevated blood pressure. CYP epoxygenase products may regulate renal function. Both 20-HETE and the EETs are generated in renal tissue; 20-HETE constricts the renal arteries, while EETs mediate vasodilation and natriuresis. Bartter syndrome is an autosomal recessive trait that manifests as hypokalemic metabolic alkalosis. The antenatal variant of Bartter syndrome is due to dysfunctional ROMK2 (Kir1.1), the K+ channel that recycles K+ into the tubular fluid. This syndrome also is known as hyperPGE syndrome. The relationship between dysfunctional ROMK2 and elevated PGE_2_ synthesis is not clear; however, in patients with antenatal Bartter syndrome, inhibition of COX-2 ameliorates many of the clinical symptoms.

**Eye**

Prostaglandin F_2α_ induces constriction of the iris sphincter muscle, but its overall effect in the eye is to decrease intraocular pressure by increasing the aqueous humor outflow. A variety of FP agonists have proven effective in the treatment of open-angle glaucoma, a condition associated with the loss of COX-2 expression in the pigmented epithelium of the ciliary body (see Chapter 69).

**Central Nervous System**

Prostaglandin E_2_ induces fever. The hypothalamus regulates the body temperature set point, which is elevated by endogenous pyrogens such as IL-1β, IL-6, TNF-α, and interferons (Morrison and Nakamura, 2011). The response is mediated by coordinate induction of COX-2 and mPGES-1 in the endothelium of blood vessels in the preoptic hypothalamic area to form PGE_2_. PGE_2_ can cross the blood-brain barrier and act on the EP_2_, and perhaps EP_3_ on thermosensitive neurons, triggering the hypothalamus to elevate body temperature. Exogenous PGF_2α_ and PGI_2_ induce fever but do not contribute to the endogenous pyretic response. PGD_2_ appears to act on arachidonic trabecular cells in the basal forebrain to mediate an increase in extracellular adenosine that, in turn, facilitates induction of sleep. COX–2–derived prostanooids also have been implicated in the pathogenesis of several CNS degenerative disorders (e.g., Alzheimer disease, Parkinson disease; see Chapter 18).

**Pain**

Inflammatory mediators, including LTs and PGs, increase the sensitivity of nociceptors and potentiate pain perception. Centrally, both COX-1 and COX-2 are expressed in the spinal cord under basal conditions and release PGs in response to peripheral pain stimuli. Both PGE_2_, through the EP_1_ and EP_3_, and PGD_2_, via the IP_, reduce the threshold to stimulation of nociceptors, causing “peripheral sensitization.” PGE_2_ and perhaps PGD_2_, PGI_2_, and PGF_2α_ can increase excitability in pain transmission neuronal pathways in the spinal cord, causing hyperalgesia and allodynia. LTB_4_ also produces hyperalgesia. The release of these eicosanoids during the inflammatory process thus serves as an amplification system for the pain mechanism. The role of PGE_2_ and PGI_2_ in inflammatory pain is discussed in more detail in Chapter 38.

**Endocrine System**

The systemic administration of PGE_2_ increases circulating concentrations of ACTH, growth hormone, prolactin, and gonadotropins. Other effects include stimulation of steroid production by the adrenals, stimulation of insulin release, and thyrotropin-like effects on the thyroid. PGE_2_ works as part of a positive-feedback loop to induce oocyte maturation required for fertilization during and after ovulation. The critical role of PGE_2_ in parturition relies on its ability to induce an oxytocin-dependent decline in progesterone levels. LOX metabolites also have endocrine effects. 12-HETE stimulates the release of aldosterone from the adrenal cortex and mediates a portion of the aldosterone release stimulated by AngII, but not that which occurs in response to ACTH.

**Bone**

Prostaglandins are strong modulators of bone metabolism. COX-1 is expressed in normal bone, while COX-2 is upregulated in settings such as inflammation and during mechanical stress. PGE_2_ stimulates bone formation by increasing osteoblastogenesis and bone resorption via activation of osteoclasts.

**Cancer**

Pharmacological inhibition or genetic deletion of COX-2 restrains tumor formation in models of colon, breast, lung, and other cancers. Large human epidemiological studies reported that the incidental use of NSAIDs is associated with significant reductions in relative risk for developing these and other cancers. PGE_2_ has been implicated as the primary pro-oncogenic prostanooid in multiple studies.

**Therapeutic Uses**

**Inhibitors and Antagonists**

The NSAIDs are used widely as anti-inflammatory drugs, whereas low-dose aspirin is employed frequently for cardioprotection (see Chapter 69). LT antagonists are useful clinically in the treatment of asthma, and FP agonists are used in the treatment of open-angle glaucoma (see Chapter 69). EP antagonists are used to induce labor and to ameliorate gastric irritation owing to NSAIDs. DP_3_ antagonists may be useful in offsetting the facial flushing associated with niacin. Orally active antagonists of LTC_4_ and D_2_, which block the CysLT, are used in the treatment of asthma that is mild to moderately severe (see Chapter 40). Their effectiveness in patients with aspirin-induced asthma also has been shown.

**Prostanoids and Their Analogues**

Prostanoids have a short t_1/2_ in the circulation, and their systemic administration produces significant adverse effects. Nonetheless, several prostanoids are of clinical utility in the following situations.

**Labor and Therapeutic Abortion**

Prostaglandin E_2_, PGF_2α_, and their analogues are used to induce labor at term and terminate pregnancy at any stage by promoting uterine contractions. These agents facilitate labor by promoting ripening and dilatation of the cervix. Dinoprost or misoprostol, synthetic analogues of PGE_2_ and PGE_2_, are used for cervical ripening and induction of labor and as abortifacients in the second trimester of pregnancy. Misoprostol, in combination with the antiprogestrone mifepristone (RU486), is highly effective in the termination of pregnancy.
An analogue of PGF₂α, carprost tromethamine, is used to induce second-trimester abortions and to control postpartum hemorrhage that does not respond to conventional methods.

**Maintenance of Patent Ductus Arteriosus.** The ductus arteriosus in neonates is highly sensitive to vasodilatation by PGE₂. Maintenance of a patent ductus may be important hemodynamically in some neonates with congenital heart disease. PGE₃ (alprostadil) is highly effective for palliative therapy to maintain temporary patency until surgery can be performed. Apnea is observed in about 10% of neonates treated, particularly those who weigh less than 2 kg at birth.

**Gastric Cytoprotection.** Several PG analogues are used to suppress gastric ulceration. Misoprostol, a PGE₁ analogue, is approved for prevention of NSAID-induced gastric ulcers and is about as effective as the proton pump inhibitor omeprazole (Chapter 49).

**Impotence.** Prostaglandin E₁ (alprostadil), given as an intracavernous injection or urethral suppository, is a second-line treatment of erectile dysfunction. Phosphodiesterase 5 inhibitors (e.g., sildenafil, tadalafil, vardenafil, and avanafil; see Chapter 41) have superseded PGE₁ as the preferred treatment of this condition.

**Pulmonary Hypertension.** Long-term therapy with PGI₂ (epoprostenol), via continuous intravenous infusion, improves symptoms and can delay or preclude the need for lung or heart-lung transplantation in a number of patients. Several orally available PGI₂ analogues with longer t₁/₂ have been used clinically. Iloprost can be inhaled or delivered by intravenous administration (injectable form is not available in the U.S.). Treprostinil (t₁/₂ = 4 h) may be delivered by continuous subcutaneous or intravenous infusion. Chapter 31 presents a comprehensive picture of the treatment of pulmonary artery hypertension.

**Glucoma.** Latanoprost, a stable, long-acting PGF₂α derivative, was the first prostanoid used for glaucoma. Similar prostanoids with ocular hypotensive effects include bimatoprost, tafluprost, and travoprost. These drugs act as agonists at the FP and are administered as ophthalmic drops (see Chapter 69).

**Platelet-Activating Factor**

In 1971, Henson demonstrated that a soluble factor released from leukocytes caused platelets to aggregate. Benveniste and his coworkers characterized the factor as a polar lipid and named it platelet-activating factor. During this period, Muirhead described an antihypertensive polar renal lipid and named it platelet-activating factor (PAF). Independent determination of the structures of PAF and PAF-like molecules can be formed from oxidized phospholipids (oxPLs) (Stafforini et al., 2003). These compounds are increased in settings of oxidant stress, such as cigarette smoking, and differ structurally from PAF in that they contain a fatty acid at the sn-1 position of glycerol joined through an ester bond and various short-chain acyl groups at the sn-2 position. oxPLs mimic the structure of PAF, bind to its receptor, and elicit the same responses. Unlike the synthesis of PAF, which is highly controlled, oxPL production is unregulated. Degradation of oxPLs by PAF-ARH is therefore necessary to suppress toxicity. Increased levels of plasma PAF-ARH have been reported in colon cancer, cardiovascular disease, and stroke.

**Sites of PAF Synthesis**

Platelet-activating factor is not stored in cells but is synthesized in response to stimulation. PAF is synthesized by platelets, neutrophils, monocytes, mast cells, eosinophils, renal mesangial cells, renal medullary cells, and vascular endothelial cells. Depending on cell type, PAF can either remain cell associated or be secreted. For example, PAF is released from monocytes but retained by leukocytes and endothelial cells. In endothelial cells, synthesis of eicosanoids and PAF depends on PLA₂ activity. The major biosynthetic pathway for PAF, the remodeling pathway, involves the precursor 1-O-alkyl-2-acyl-glycerophosphocholine, a membrane lipid; the 2-acyl substituents include AA. PAF is synthesized from this substrate in two steps (Figure 37–5). The rate-limiting step is the second one, acetyl-coenzyme-A-lyso-PAF acetytransferase. The synthesis of PAF may be stimulated during antigen-antibody reactions or by a variety of agents, including chemotactic peptides, thrombin, collagen, and other autacoids; PAF also can stimulate its own formation. Both the PL and acetytransferase are Ca²⁺-dependent enzymes; thus, PAF synthesis is regulated by the availability of Ca²⁺. The inactivation of PAF is catalyzed by PAF-ARH. PAF is inactivated by PAF-ARH–catalyzed hydrolysis of the acetyl group, generating Lyso-PAF, which is then converted to a 1-O-alkyl-2-acyl-glycerophosphocholine by an acyltransferase (McIntyre et al., 2009; Stafforini et al., 2003).

Synthesis of PAF also can occur de novo by transfer of a phosphocholine substituent to alkyl acyl glycerol by a lyso-glycerophosphate acetyl–coenzyme A transferase. This pathway may contribute to physiological levels of PAF for normal cellular functions. PAF-like molecules can be formed from oxidized phospholipids (oxPLs) (Stafforini et al., 2003). These compounds are increased in settings of oxidant stress, such as cigarette smoking, and differ structurally from PAF in that they contain a fatty acid at the sn-1 position of glycerol joined through an ester bond and various short-chain acyl groups at the sn-2 position. oxPLs mimic the structure of PAF, bind to its receptor, and elicit the same responses. Unlike the synthesis of PAF, which is highly controlled, oxPL production is unregulated. Degradation of oxPLs by PAF-ARH is therefore necessary to suppress toxicity. Increased levels of plasma PAF-ARH have been reported in colon cancer, cardiovascular disease, and stroke.
PAF is displayed on the surface for juxtacrine signaling and stimulates adherent leukocytes.

**Mechanism of Action of PAF**

Extracellular PAF exerts its actions by stimulating a specific GPCR (Honda et al., 2002). The PAF receptor couples to Gq (to activate the PLC-IP, -Ca²⁺-pathway) and to Gi (to inhibit adenyl cyclase). Consequent activation of PLs A₂, C, and D gives rise to second messengers, including AA-derived PGs, TxA₂, or LTs, which may function as mediators of the effects of PAF.

In addition, p38 mitogen-activated protein kinase is activated downstream of the PAF-receptor–Gq interaction, while extracellular signal–regulated kinase activation can occur via interaction of activated PAF receptor with Gq, Go, or their βγ subunits, or via transactivation of the EGF receptor, leading to nuclear factor kappa B activation. PAF exerts many of its important pro-inflammatory actions without leaving its cell of origin. For example, PAF is synthesized in a regulated fashion by endothelial cells stimulated by inflammatory mediators. This PAF is presented on the surface of the endothelium, where it activates the PAF receptor on juxtaposed cells, including platelets, PMNs, and monocytes, and acts cooperatively with P selectin to promote adhesion. This function of PAF is important for orchestrating the interaction of platelets and circulating inflammatory cells with the inflamed endothelium.

**Physiological and Pathological Functions of PAF**

Platelet-activating factor generally is viewed as a mediator of pathological events and has been implicated in allergic asthma, endotoxic shock, acute pancreatitis, certain cancers, dermal inflammation, and inflammatory cardiovascular diseases such as atherosclerosis.

**Inflammatory and Allergic Responses**

Experimental administration of PAF reproduces many of the signs and symptoms in anaphylactic shock. However, the effects of PAF antagonists in the treatment of inflammatory and allergic disorders have been disappointing. In patients with asthma, PAF antagonists partially inhibit the bronchoconstriction induced by antigen challenge but not by challenges by methacholine, exercise, or inhalation of cold air. These results may reflect the complexity of these pathological conditions and the likelihood that other mediators contribute to the inflammation associated with these disorders.

**Cardiovascular System**

Platelet-activating factor is a potent vasodilator in most vascular beds; when administered intravenously, it causes hypotension. PAF-induced vasodilation is independent of effects on sympathetic innervation, the renin-angiotensin system, or AA metabolism and likely results from a combination of direct and indirect actions. PAF may, alternatively, induce vasoconstriction depending on the concentration, vascular bed, and involvement of platelets or leukocytes. For example, the intracoronary administration of very low concentrations of PAF increases coronary blood flow by a mechanism that involves the release of a platelet-derived vasodilator. Coronary blood flow is decreased at higher doses by the formation of intravascular aggregates of platelets or the formation of TxA₂. The pulmonary vasculature also is constricted by PAF, and a similar mechanism is thought to be involved.

Intradermal injection of PAF causes an initial vasoconstriction followed by a typical wheal and flare. PAF increases vascular permeability and edema in the same manner as histamine and bradykinin. The increase in permeability is due to contraction of venular endothelial cells, but PAF is more potent than histamine or bradykinin by three orders of magnitude.

**Platelets**

The PAF receptor is constitutively expressed on the surface of platelets. PAF potently stimulates platelet aggregation. The intravenous injection of PAF causes formation of intravascular platelet aggregates and thrombocytopenia. Although this is accompanied by the release of TxA₂ and the granular contents of the platelet, PAF does not require the presence of TxA₂ or other aggregating agents to produce this effect. PAF antagonists fail to block thrombin-induced aggregation, even though they prolong bleeding time and prevent thrombus formation in some experimental models. Thus, PAF may contribute to thrombus formation, but it does not function as an independent mediator of platelet aggregation.

**Leukocytes**

Platelet-activating factor is a potent and common activator of inflammatory cells. PAF stimulates a variety of responses in PMNs (eosinophils, neutrophils, and basophils). PAF stimulates PMNs to aggregate, degranulate, and generate free radicals and LTs. PAF is a potent chemotactic for eosinophils, neutrophils, and monocytes and promotes PMN-endothelial adhesion contributing, along with other adhesion molecular systems, to leukocyte rolling, tight adhesion, and migration through the endothelial monolayer. PAF also stimulates basophils to release histamine, activates mast cells, and induces cytokine release from monocytes. In addition, PAF promotes aggregation of monocytes and degranulation of eosinophils.

**Smooth Muscle**

Platelet-activating factor contracts GI, uterine, and pulmonary smooth muscle. PAF enhances the amplitude of spontaneous uterine contractions; these contractions are inhibited by inhibitors of PG synthesis. PAF does not affect tracheal smooth muscle but contracts airway smooth muscle. When given by aerosol, PAF increases airway resistance as well as the responsiveness to other bronchoconstrictors. PAF also increases mucus secretion and the permeability of pulmonary microvessels.

**Stomach**

In addition to contracting the fundus of the stomach, PAF is the most potent known ulcerogen. When given intravenously, it causes hemorrhagic erosions of the gastric mucosa that extend into the submucosa.

**Kidney**

Platelet-activating factor decreases renal blood flow, glomerular filtration rate, urine volume, and excretion of Na⁺ without changes in systemic hemodynamics. PAF exerts a receptor-mediated biphasic effect on afferent arterioles, dilating them at low concentrations and contracting them at higher concentrations. The vasoconstrictor effect appears to be mediated, at least in part, by COX products, whereas vasodilation is a consequence of the stimulation of NO production by endothelium.

**Other**

Platelet-activating factor, a potent mediator of angiogenesis, has been implicated in breast and prostate cancer. PAF-AH deficiency has been associated with small increases in a range of cardiovascular and thrombotic diseases in some human populations.

**PAF Receptor Antagonists**

Several experimental PAF receptor antagonists exist that selectively inhibit the actions of PAF in vivo and in vitro. None has proven clinically useful. Thus, synthetic PAF, when administered in sufficient quantities, exerts a broad spectrum of effects. However, the evidence of its importance as an endogenous mediator remains to be established. Interestingly, inhibition of PAF-AH, which would be expected to elevate endogenous levels of PAF, was pursued as the protein also functions as a lipoprotein-associated PLA₂. Trials of an inhibitor, darapladib, failed to establish either clinical efficacy attributable to eicosanoid suppression or an adverse effect profile potentially attributable to increased levels of PAF (O’Donoghue et al., 2014).

Bibliography

Powell WS, Rokach J. Biosynthesis, biological effects, and receptors of hydroxyeicosatetraenoic acids (HETEs) and oxoicosatetraenoic acids (oxo-ETEs) derived from arachidonic acid. *Biochim Biophys Acta*, 2015, 1851:340–355.
This chapter describes the non-steroidal anti-inflammatory drugs (NSAIDs) used to treat inflammation, pain, and fever and the drugs used for hyperuricemia and gout. The NSAIDs are first considered by class, then by groups of chemically similar agents described in more detail. Many of the basic properties of these drugs are summarized in Tables 38–1, 38–2, and 38–3.

The NSAIDs act by inhibiting the prostaglandin (PG) G/H synthase enzymes, colloquially known as the cyclooxygenases (COXs) (see Chapter 37). There are two forms, COX-1 and COX-2. The inhibition of COX-2 is thought to mediate, in large part, the antipyretic, analgesic, and anti-inflammatory actions of NSAIDs. Adverse reactions are largely caused by the inhibition of COX-1 and COX-2 in tissues in which they fulfill physiological functions, such as the GI tract, the kidney, and the cardiovascular system. Aspirin is the only irreversible inhibitor of the COX enzymes in clinical use. All other NSAIDs bind the COXs reversibly and act either by competing directly with arachidonic acid (AA) at the active site of COX-1 and COX-2 or by changing their steric confirmation in a way that alters their ability to bind arachidonic acid. Acetaminophen (paracetamol) is effective as an antipyretic and analgesic agent at typical doses that partly inhibit COXs and has only weak anti-inflammatory activity. Purposefully designed selective inhibitors of COX-2 (celecoxib, etoricoxib) are a subclass of NSAIDs; several of the older traditional NSAIDs, such as diclofenac and meloxicam (see Figure 38–1) also selectively inhibit COX-2 at therapeutic doses.

**HISTORICAL PERSPECTIVE**

The history of aspirin provides an interesting example of the translation of a compound from the realm of herbal folklore to contemporary therapeutics. The use of willow bark and leaves to relieve fever has been attributed to Hippocrates but was most clearly documented by Edmund Stone in a 1763 letter to the president of the Royal Society. Similar properties were attributed to potions from meadowsweet (*Spiraea ulmaria*), from which the name aspirin is derived. Salicin was crystallized in 1829 by Leroux, and Pina isolated salicylic acid in 1836. In 1859, Kolbe synthesized salicylic acid, and by 1874, it was being produced industrially. It soon was being used for rheumatic fever and gout and as a general antipyretic. However, its unpleasant taste and adverse GI effects made it difficult to tolerate for more than short periods. In 1899, Hoffmann, a chemist at Bayer Laboratories, sought to improve the adverse effect profile of salicylic acid (which his father was taking for arthritis). Hoffmann came across the earlier work of the French chemist Gerhardt, who had acetylated salicylic acid in 1853, apparently ameliorating its adverse effect profile, but without improving its efficacy, and therefore abandoned the project. Hoffmann resumed the quest, and Bayer began testing acetylsalicylic acid (ASA) in animals by 1899 and proceeded soon thereafter to human studies and the marketing of aspirin.

Acetaminophen was first used in medicine by von Mering in 1893. However, it gained popularity only after 1949, when it was recognized as the major active metabolite of both acetaminol and phenacetin. Acetaminol is the parent member of this group of drugs. It was introduced into medicine in 1886 under the name antifebrin by Cahn and Hepp, who had discovered its antipyretic action accidentally. However, acetaminol proved to be excessively toxic. A number of chemical derivatives were developed and tested. One of the more satisfactory of these was phenacetin. It was introduced into therapy in 1887 and was extensively employed in analgesic mixtures until it was implicated in analgesic abuse nephropathy, hemolytic anemia, and bladder cancer; it was withdrawn in the 1980s.
Abbreviations

AA: arachidonic acid  
ACE: angiotensin-converting enzyme  
ASA: acetylsalicylic acid/aspirin  
AUC: area under the curve  
COX: cyclooxygenase  
CSF: cerebrospinal fluid  
G6PD: glucose-6-phosphate dehydrogenase  
GSH: glutathione  
15(R)-HETE: 15(R)-hydroxyeicosatetraenoic acid  
5-HIAA: 5-hydroxyindoleacetic acid  
SHT: 5-hydroxytryptamine/serotonin  
Ig: immunoglobulin  
IL: interleukin  
IM: intramuscular  
IV: intravenous  
LOX: lipooxygenase  
LT: leukotriene  
MI: myocardial infarction  
NAC: N-acetylcysteine  
NAPQI: N-acetyl-p-benzoquinone imine  
NSAID: nonsteroidal anti-inflammatory drug  
OAT: organic anion transporter  
OC: over the counter  
PAF: platelet-activating factor  
PG: prostaglandin  
PGI2: prostacyclin  
PAF: platelet-activating factor  
PPI: proton pump inhibitor  
TNF: tumor necrosis factor  
Tx: thromboxane  
UGT: uridine diphosphate glucuronosyltransferase  
URAT: urate transporter  
XO: xanthine oxidase

without apparent benefit and even with severe adverse consequences (e.g., hypersensitivity, autoimmune diseases, chronic inflammation). The inflammatory response is characterized mechanistically by:

- transient local vasodilation and increased capillary permeability;
- infiltration of leukocytes and phagocytic cells; and
- resolution with or without tissue degeneration and fibrosis.

Many molecules are involved in the promotion and resolution of the inflammatory process. Histamine, bradykinin, SHT, prostanooids, LTs, PAF, and an array of cytokines are important mediators (see Chapters 34, 37, and 39). Prostanoid biosynthesis is significantly increased in inflamed tissue. PGE, and prostacyclin (PGI₂) are the primary prostanoids that mediate inflammation. They increase local blood flow, vascular permeability, and leukocyte infiltration through activation of their respective receptors, EP₃, and IP. PGD₂, a major product of mast cells, contributes to inflammation in allergic responses, particularly in the lung.

Activation of endothelial cells plays a key role in recruiting circulating cells to inflammatory sites (Muller, 2011). Endothelial activation results in leukocyte rolling and adhesion as the leukocytes recognize newly expressed selectins, integrins, and adhesion molecules. PGE₂ and TxA₂ enhance leukocyte chemoattraction and endothelial adhesion.

The recruitment of inflammatory cells to sites of injury also involves the concerted interactions of the complement factors PAF, and eicosanoids such as LTβ (see Chapter 37). All can act as chemotactic agonists. Cytokines play essential roles in orchestrating the inflammatory process, especially TNF and IL-1. Several biological anti-inflammatory therapeutics target these cytokines or their signaling pathways (see Chapter 35). Other cytokines and growth factors (e.g., IL-2, IL-6, IL-8, granulocyte-macrophage colony-stimulating factor) contribute to manifestations of the inflammatory response. The concentrations of many of these factors are increased in the synovia of patients with inflammatory arthritis. Glucocorticoids interfere with the synthesis and actions of cytokines, such as IL-1 or TNF-α (see Chapter 35). Although some of the actions of these cytokines are accompanied by the release of PGs and TxA₂, COX inhibitors appear to block primarily their pyrogenic effects.
**Pain**

Nociceptors, peripheral terminals of primary afferent fibers that sense pain, can be activated by various stimuli, such as heat, acids, or pressure. Inflammatory mediators released from nonneuronal cells during tissue injury increase the sensitivity of nociceptors and potentiate pain perception. Among these mediators are bradykinin, H⁺, SHT, ATP, neurotrophins (nerve growth factor), LTB₄, and PGs. PGE, and PGF₉α, reduce the threshold to stimulation of nociceptors, causing *peripheral sensitization*. Reversal of peripheral sensitization is thought to represent the mechanistic basis for the peripheral component of the analgesic activity of NSAIDs. NSAIDs may also have important central actions in the spinal cord and brain. Both COX-1 and COX-2 are expressed in the spinal cord under basal conditions and release PGs in response to peripheral pain stimuli.

Centrally active PGE₉, and perhaps also PGD₂, PGI₂, and PGF₁α, contribute to *central sensitization*, an increase in excitability of spinal dorsal horn neurons that causes hyperalgesia and allodynia in part by disinhibition of glycnergic pathways (Chen et al., 2013). Central sensitization reflects the plasticity of the nociceptive system that is invoked by injury. This usually is reversible within hours to days following adequate responses of the nociceptive system (e.g., in postoperative pain). However, chronic inflammatory diseases may cause persistent modification of the architecture of the nociceptive system, which may lead to long-lasting changes in its responsiveness. These mechanisms contribute to chronic pain.

**Fever**

The hypothalamus regulates the set point at which body temperature is maintained. This set point is elevated in fever, reflecting an infection, or resulting from tissue damage, inflammation, graft rejection, or malignancy. These conditions all enhance formation of cytokines such as IL-1β, IL-6, TNF-α, and interferons, which act as endogenous pyrogens. The initial phase of the thermoregulatory response to such pyrogens may be mediated by ceramide release in neurons of the preoptic area in the anterior hypothalamus (Sanchez-Alavez et al., 2006). The second phase is mediated by coordinate induction of COX-2 and formation of PGE₂ (Engblom et al., 2003). PGE₂ can cross the blood-brain barrier and acts on EP₃ receptors, which increase body temperature by promoting an increase in heat generation and a decrease in heat loss. NSAIDs suppress this response by inhibiting COX-2-dependent PGE₂ synthesis.

**Mechanism of Action**

**Cyclooxygenase Inhibition**

The principal therapeutic effects of NSAIDs derive from their ability to inhibit PG production. The first enzyme in the PG synthetic pathway is COX, also known as PG G/H synthase. This enzyme converts AA to the unstable intermediates PGG₂ and PGG₁, and leads to the production of the prostanooids, TxA₃, and a variety of PGs (see Chapter 37). COX-1, expressed constitutively in most cells, is the dominant source of prostanooids for housekeeping functions, such as hemostasis. Conversely, COX-2, induced by cytokines, shear stress, and tumor promoters, is the more important source of prostanooid formation in inflammation and perhaps in cancer (see Chapter 37). However, both enzymes contribute to the generation of autoregulatory and homeostatic prostanooids with important functions in normal physiology (see Chapter 37). The indiscriminant inhibition of both inflammatory and homeostatic prostanooids by NSAIDs explains mechanistically most adverse reactions to this drug class. For example, inhibition of COX-1 accounts largely for the gastric adverse events and bleeding that complicate therapy because COX-1 is the dominant cytoprotective isoform in gastric epithelial cells and forms TxA₃, which amplifies platelet activation and constricts blood vessels at the site of injury. Similarly, COX-2–derived products play important roles in blood pressure regulation and act as endogenous inhibitors of hemostasis. Inhibition of COX-2 can cause or exacerbate hypertension and increases the likelihood of thrombotic events.

While the functional COX enzymes are sequence homodimers, they are configured as conformational heterodimers in which one of the mono- mers functions as the catalytic subunit with heme bound and the other, without heme, serves as the allosteric subunit. Most NSAIDs inhibit the catalytic subunits of COX-1 and COX-2. However, COX-2 inhibition by naproxen, and flurbiprofen occurs primarily on the allosteric subunit (Dong et al., 2011; Zou et al., 2012).

**Irreversible Cyclooxygenase Inhibition by Aspirin**

Aspirin covalently acetylates the catalytic subunits of the COX-1 and COX-2 dimers, irreversibly inhibiting COX activity. This is an important distinction from all the other NSAIDs because the duration of aspirin’s effects is related to the turnover rate of the COXs in different target tissues.

The importance of enzyme turnover in recovery from aspirin action is most notable in platelets, which, being anucleate, have a markedly limited capacity for protein synthesis. Thus, the consequences of inhibition of platelet COX-1 last for the lifetime of the platelet. Inhibition of platelet COX-1–dependent TxA₃ formation is therefore cumulative with repeated doses of aspirin (at least as low as 30 mg/d) and takes 8–12 days (the platelet turnover time) to recover fully once therapy has been stopped. Importantly, even a partially recovered platelet pool—just a few days after the last aspirin dose—may afford recovery of sufficient hemostatic integrity for some types of elective surgery to be performed. However, such a partial platelet function also may predispose noncompliant patients on low-dose aspirin for antiplatelet therapy to thrombotic events. The unique sensitivity of platelets to inhibition by low doses of aspirin is related to their presystemic inhibition in the portal circulation before aspirin is deacetylated to salicylate on first pass through the liver (Pedersen and FitzGerald, 1984). In contrast to aspirin, salicylic acid has no acetylator capacity. It is a relatively weak, irreversible inhibitor of COX. Salicylic acid derivatives, rather than the acid, are available for clinical use.

The COXs are configured such that the active site is accessed by the AA substrate via a hydrophobic channel. Aspirin acetylates serine 529 of COX-1, located high up in the hydrophobic channel. Interposition of the bulky acetyl residue prevents the binding of AA to the active site of the enzyme and thus impedes the ability of the enzyme to make PGs. Aspirin acetylates a homologous serine at position 516 in COX-2. Although covalent modification of COX-2 by aspirin also blocks the COX activity of this isoform, an interesting property not shared by COX-1 is that acetylated COX-2 synthesizes 15(R)-HETE. This may be metabolized, at least in vitro, by 5-LOX to yield 15-epi-lipoxin A₃, which has anti-inflammatory properties in model systems (see Chapter 37).

**Nonsteroidal Anti-inflammatory Drugs**

The NSAIDs are mechanistically classified as *isofom nonselective NSAIDs*, which inhibit both COX-1 and COX-2, and *COX-2–selective NSAIDs* (FitzGerald and Patrono, 2001). Most NSAIDs are competitive, noncompetitive, or mixed reversible inhibitors of the COX enzymes. Aspirin (ASA) is a noncompetitive, irreversible inhibitor because it acetylates the isozymes in the AA-binding channel. Acetaminophen, which is antipyretic and analgesic but largely devoid of anti-inflammatory activity, acts as a noncompetitive reversible inhibitor by reducing the peroxide site of the enzymes.

The majority of NSAIDs are organic acids with relatively low pKa values. As organic acids, the compounds generally are well absorbed orally, highly bound to plasma proteins, and excreted either by glomerular filtration or by tubular secretion. They also accumulate in sites of inflammation, bound to plasma proteins, and excreted either by glomerular filtration or by tubular secretion. They also accumulate in sites of inflammation, bound to plasma proteins, and excreted either by glomerular filtration or by tubular secretion.
Selective Inhibition of Cyclooxygenase 2

The chronic use of the NSAIDs is limited by their poor GI tolerability. Selective inhibitors of COX-2 were developed to afford efficacy similar to traditional NSAIDs with better GI tolerability (FitzGerald and Patrone, 2001). Six such COX-2 inhibitors, the coxibs, were initially approved for clinical use: celecoxib, rofecoxib, valdecoxib (approved in the U.S.) and its produg parecoxib, etoricoxib, and lumiracoxib. Most coxibs have been either restricted in their use or withdrawn from the market in view of their adverse cardiovascular risk profile (Grosser et al., 2010). Celecoxib currently is the only COX-2 inhibitor licensed for use in the U.S. Some older NSAID compounds—diclofenac, etodolac, meloxicam, and nimesulide (the last not available in the U.S.)—exhibit selectivity for COX-2 that is close to that of celecoxib (Figure 38–1).

ADME

Absorption. The NSAIDs are rapidly absorbed following oral ingestion, and peak plasma concentrations are reached within 2–3 h. The poor aqueous solubility of most NSAIDs often is reflected by a less-than-proportional increase in the AUC of plasma concentration–time curves, due to incomplete dissolution, when the dose is increased. Food intake may delay absorption and systemic availability (i.e., fenoprofen, sulindac). Antacids, commonly prescribed to patients on NSAID therapy, variably delay absorption. Some compounds (e.g., diclofenac, nabumetone) undergo first-pass and presystemic elimination. Aspirin begins to acetylate platelets within minutes of reaching the presystemic circulation (Pedersen and FitzGerald, 1984).

Distribution. Most NSAIDs are extensively bound (95%–99%) to plasma proteins, usually albumin. Conditions that alter plasma protein concentration may result in an increased free drug fraction with potential toxic effects. Highly protein bound NSAIDs have the potential to displace other drugs if they compete for the same binding sites. Most NSAIDs are distributed widely throughout the body and readily penetrate arthritic joints, yielding synovial fluid concentrations in the range of half the plasma concentration (i.e., ibuprofen, naproxen, piroxicam) (Day et al., 1999). Most NSAIDs achieve sufficient concentrations in the CNS to have a central analgesic effect. Celecoxib is particularly lipophilic and moves readily into the CNS. Multiple NSAIDs are marketed in formulations for topical application on inflamed or injured joints. However, direct transport of topically applied NSAIDs into inflamed tissues and joints appears to be minimal, and detectable concentrations in synovial fluid of some agents (i.e., diclofenac) following topical use are primarily attained via dermal absorption and systemic circulation. Methods designed to enhance transdermal delivery, such as iontophoresis or chemical penetration enhancers, are under investigation. Topical application is also being explored as a delivery route for drug combinations containing narcotics and NSAIDs.

Metabolism and Excretion. Hepatic biotransformation and renal excretion are the principal routes of metabolism and elimination of the majority of NSAIDs. Plasma t\text{1/2} varies considerably among NSAIDs. Ibuprofen, diclofenac, and acetaminophen have a t\text{1/2} ranging from 9 to 25 h. Genetic variation in the major metabolizing enzymes and variation in the composition of intestinal microbiota may contribute to variability in metabolism and elimination. Elimination pathways frequently involve oxidation or hydroxylation. Acetaminophen, at therapeutic doses, is oxidized only to a small degree to form traces of the highly reactive metabolite NAPQI. Following overdose, however, the principal metabolic pathways are saturated, and hepatotoxic NAPQI concentrations can be formed (see Figure 4–5). Several NSAIDs or their metabolites are glucuronidated or otherwise conjugated. In some cases, such as the propionic acid derivatives naproxen and ketoprofen, the glucuronide metabolites can hydrolyze back to form the active parent drug when the metabolite is not removed efficiently due to renal insufficiency or competition for renal excretion with other drugs. This may prolong elimination of the NSAID significantly. In general, NSAIDs are not recommended in the setting of advanced hepatic or renal disease due to their adverse pharmacodynamic effects. NSAIDs usually are not removed by hemodialysis due to their extensive plasma protein binding; salicylic acid is an exception to this rule.

Therapeutic Uses

The NSAIDs are antipyretic, analgesic, and anti-inflammatory, with the exception of acetaminophen, which is antipyretic and analgesic but is largely devoid of anti-inflammatory activity.

Inflammation

The NSAIDs provide mostly symptomatic relief from pain and inflammation associated with musculoskeletal disorders, such as rheumatoid arthritis and osteoarthritis. Some NSAIDs are approved for the treatment of ankylosing spondylitis and gout. Patients with more debilitating disease may not respond adequately to full therapeutic doses of NSAIDs and may require aggressive therapy with second-line agents.

Pain

The NSAIDs are effective against inflammatory pain of low-to-moderate intensity. Although their maximal efficacy is generally less than the opioids, NSAIDs lack the unwanted adverse effects of opiates in the CNS, including respiratory depression and the potential for development of physical dependence. Co-administration of NSAIDs can reduce the opioid dose needed for sufficient pain control and reduce the likelihood of adverse opioid effects. For example, acetaminophen can be prescribed in combination with hydrocodone. NSAIDs do not change the perception of sensory modalities other than pain. NSAIDs are particularly effective when inflammation has caused sensitization of pain perception (see other discussion in this section on inflammation, pain, and fever). Thus, postoperative pain or pain arising from inflammation, such as arthritic pain, is controlled well by NSAIDs, whereas pain arising from the hollow viscera usually is not relieved. An exception to this is menstrual pain. Treatment of menstrual pain with NSAIDs has met with considerable success because cramps and other symptoms of primary dysmenorrhea are caused by the release of PGS by the endometrium during menstruation. NSAIDs are commonly used to treat migraine attacks and can be combined with drugs such as the triptans or with antiemetics to aid relief of the associated nausea. NSAIDs generally lack efficacy in neuropathic pain.

Fever

Antipyretic therapy is reserved for patients in whom fever in itself may be deleterious and for those who experience considerable relief when fever is lowered. NSAIDs reduce fever in most situations, but not the circadian variation in temperature or the rise in response to exercise or increased ambient temperature.

Fetal Circulatory System

The PGs are implicated in the maintenance of patency of the ductus arteriosus, and indomethacin, ibuprofen, and other NSAIDs have been used in neonates to close the inappropriately patent ductus. Conversely, infusion of prostandoid analogues maintains ductal patency after birth (see Chapter 37).

Cardioprotection

Ingestion of aspirin prolongs bleeding time. This effect is due to irreversible acetylation of platelet COX and the consequent inhibition of platelet function. It is the permanent suppression of platelet TxA\textsubscript{2} formation that is thought to underlie the cardioprotective effect of aspirin. Aspirin reduces the risk of serious vascular events in high-risk patients (e.g., those with previous myocardial infarction) by 20%–25%. The reduction of subsequent thrombotic strokes is somewhat less, roughly 10%–15% (Antithrombotic Trialists’ Collaboration et al., 2009). Low-dose aspirin (≤100 mg/d) is associated with a lower risk for GI adverse events than higher doses (e.g., 325 mg/d) and is often used following percutaneous coronary intervention (Xian et al., 2015). Low doses of aspirin are associated with a small (roughly 2-fold) but detectable increase in the incidence of serious GI bleeds and intracranial bleeds in placebo-controlled trials. The benefit from aspirin, however, outweighs these risks in the case of secondary prevention of cardiovascular disease. The issue is much more nuanced in patients who have never had a serious atherothrombotic
event (primary prevention); here, prevention of myocardial infarction by aspirin is numerically balanced by the serious GI bleeds it precipitates (Patrono, 2015). Given their relatively short t½ and reversible COX inhibition, most other NSAIDs are not thought to afford cardioprotection. Data suggest that cardioprotection is lost when combining low-dose aspirin with NSAIDs through a drug-drug interaction at the aspirin target site in platelet COX-1 (Catella-Lawson et al., 2001; Farkouh et al., 2004; Li et al., 2014). COX-2–selective NSAIDs are devoid of antplatelet activity, as mature platelets do not express COX-2.

Other Clinical Uses

Systemic Mastocytosis. Systemic mastocytosis is a condition in which there are excessive mast cells in the bone marrow, reticuloendothelial system, GI system, bones, and skin (Theoharides et al., 2015). In patients with systemic mastocytosis, PGD2, released from mast cells is the major mediator of severe episodes of flushing, vasodilatation, and hypotension; this PGD2 effect is resistant to antihistamines. The addition of aspirin or ketoprofen (off-label use) may be beneficial in patients with high levels of urinary PGD metabolites who have flushing and angioedema. However, NSAIDs can cause degranulation of mast cells, so blockade with histamine receptor antagonists should be established before NSAIDs are initiated.

Niacin Tolerability. Large doses of niacin (nicotinic acid) effectively lower serum cholesterol levels, reduce low-density lipoprotein, and raise high-density lipoprotein (see Chapter 33). However, niacin induces intense facial flushing mediated largely by release of PGD2 from the skin, which can be inhibited by treatment with aspirin (Song et al., 2012).

Bartter Syndrome. Bartter syndrome includes a series of rare disorders (frequency ≤ 1/100,000 persons) characterized by hypokalemic, hypochloremic metabolic alkalosis with normal blood pressure and hyperplasia of the juxtaglomerular apparatus. Fatigue, muscle weakness, diarrhea, and dehydration are the main symptoms. Distinct variants are caused by mutations in a Na+-K+-2Cl– cotransporter, an apical ATP-regulated K+ channel, a basolateral Cl– channel, a protein (barttin) involved in cotransporter trafficking, and the extracellular Ca2+-sensing receptor. Renal COX-2 is induced, and biosynthesis of PGE2, is increased. Treatment with indomethacin, combined with potassium repletion and spironolactone, is associated with improvement in the biochemical derangements and symptoms. Selective COX-2 inhibitors also have been used (Nusing et al., 2001).

Cancer Chemoprevention. Epidemiological studies suggested that daily use of aspirin is associated with a 24% decrease in the incidence of colon cancer (Rothwell et al., 2010). Similar observations have been made with NSAID use in this and other cancers. NSAIDs have been used in patients with familial adenomatous polyposis, an inherited disorder characterized by multiple adenomatous colon polyps developing during adolescence and the inevitable occurrence of colon cancer by the sixth decade.

Adverse Effects of NSAID Therapy

Adverse events common to aspirin and NSAIDs are outlined in Table 38–1. To minimize potential adverse events of NSAIDs, the lowest effective dose should be used for the shortest feasible length of time. Age generally is correlated with an increased probability of developing serious adverse reactions to NSAIDs, and caution is warranted in choosing a lower starting dose for elderly patients. NSAIDs are labeled with a black-box warning related to cardiovascular risks and are specifically contraindicated following coronary artery bypass graft (CABG) surgery.

Gastrointestinal

The most common symptoms associated with these drugs are GI (~40% of patients), including dyspepsia, abdominal pain, anorexia, nausea, and diarrhea. However, these symptoms are not predictive of gastric or intestinal lesions such as subepithelial hemorrhages, erosions, and ulcers, which can be endoscopically detected in about 30%–50% of NSAID users, but are often asymptomatic and tend to heal spontaneously. Serious complications—bleeding, perforation, or obstruction—occur at an annual

*Refer to product label for specific information.
*Reported for most, but not all, NSAIDs.
*With the exception of low-dose aspirin.
rate of 1%–2% in regular NSAID users. Many patients who develop a serious upper GI adverse event while receiving NSAID therapy are asymptomatic prior to diagnosis. The risk is particularly high in those with *Helicobacter pylori* infection, heavy alcohol consumption, or other risk factors for mucosal injury, including the concurrent use of glucocorticoids. All selective COX-2 inhibitors are less prone to induce gastric ulcers than equally efficacious doses of isoform nonselective NSAIDs (Sostres et al., 2013). Several mechanisms contribute to NSAID-induced GI complications (see Chapter 37). Inhibition of COX-1 in gastric epithelial cells depresses mucosal cytoprotective PGs, especially PGI, and PGE. These eicosanoids inhibit acid secretion by the stomach, enhance mucosal blood flow and promote the secretion of cytoprotective mucus in the intestine. COX-2 also contributes to constitutive formation of these PGs by human gastric epithelium, and products of COX-2 may contribute to ulcer healing. Another factor that may play a part in the formation of ulcers is the local irritation from contact of orally administered NSAIDs—most of which are organic acids—with the gastric mucosa. However, the incidence of serious GI adverse events is not significantly reduced by formulations devised to limit drug contact with the gastric mucosa, such as enteric coating or effervescent solutions, suggesting that the contribution of direct irritation to the overall risk of NSAID-induced ulceration is minor. Platelet inhibition by NSAIDs increases the likelihood of blood clots when mucosal damage has occurred. Coadministration of proton pump inhibitors or H, antagonists in conjunction with NSAIDs reduces the rate of duodenal and gastric ulceration (see Chapter 49, Figure 49-1).

### Cardiovascular

The COX-2–selective NSAIDs were developed to improve GI safety. However, COX-2 inhibitors depress formation of PG, but do not inhibit the COX-1–alyzed formation of platelet TxA, PGI, inhibits platelet aggregation and constrains the effect of prothrombotic and atherogenic stimuli by TxA, (Grosser et al., 2006, 2010, 2017), and renal PGI, and PGE, formed by COX-2 contribute to arterial pressure homeostasis (see Chapter 37). Gastrointestinal irritation of the NG, receptor, IP, in vivo augments the thrombotic response to endothelial injury, accelerates experimental atherogenesis, increases vascular proliferation, and adds to the effect of hypertensive stimuli (Cheng et al., 2002, 2006; Egan et al., 2004; Kobayashi et al., 2004). Tissue-specific genetic deletion of COX-2 in the vasculature accelerates the response to thrombotic stimuli and raises blood pressure (Yu et al., 2012). Together, these mechanisms would be expected to alter the cardiovascular risk of humans, as COX-2 inhibition in humans depresses PGI, synthesis (Catella-Lawson et al., 1999; McAdam et al., 1999). Indeed, a human mutation of the IP, which disrupts its signaling, is associated with increased cardiovascular risk (Arehart et al., 2008).

Clinical trials—with celecoxib, valdecoxib (withdrawn), and rofecoxib (withdrawn)—revealed an increase in the incidence of myocardial infarction, stroke, and vascular death by approximately 1.4-fold (Coxib and Traditional NSAID Trialists’ Collaboration et al., 2013). The risk extends to diclofenac, which is almost as COX-2 selective as celecoxib, and to some of the other NSAIDs. An exception in some individuals may be naproxen. There is considerable between-person variation in the f subpopulation, and platelet inhibition might be anticipated throughout the dosing interval in some, but not all, individuals on naproxen (Capone et al., 2005). While this is supported by randomized controlled trials (Coxib and Traditional NSAID Trialists’ Collaboration et al., 2013), identifying individuals who fall into the long-acting group is currently not practical in clinical routine. The FDA has determined that the data differentiating the risk between distinct NSAIDs is not sufficient to distinguish between drugs on the regulatory level; thus, a cardiovascular risk warning is included on the label of all NSAIDs (U.S. Food and Drug Administration, 2015). Similarly, all NSAIDs share a class black-box warning contraindicating their use for the treatment of perioperative pain in the setting of CABG surgery.

The NSAIDs with selectivity for COX-2 should be reserved for patients at high risk for GI complications. The cardiovascular risk appears to be conditioned by factors influencing drug exposure, such as dose, f subpopulation, degree of COX-2 selectivity, potency, and treatment duration. Thus, the lowest possible dose should be prescribed for the shortest possible period.

### Blood Pressure and Renal Adverse Events

All NSAIDs have been associated with renal and renovascular adverse events. Up to 5% of regular NSAID users can be expected to develop hypertension. Clinical studies suggest that hypertensive complications occur more commonly in patients treated with COX-2–selective than with nonselective NSAIDs. Heart failure risk is roughly doubled.

The NSAIDs have little effect on renal function or blood pressure in healthy human subjects because of the redundancy of systems that regulate renal function. In situations that challenge the regulatory systems, such as dehydration, hypovolemia, congestive heart failure, hepatic cirrhosis, chronic kidney disease, and other states of activation of the sympathetic renal or renin-angiotensin systems, regulation of renal function by PG formation becomes crucial (see Chapter 37). NSAIDs impair the PG–induced inhibition of both the reabsorption of Cl and the action of antidiuretic hormone, which may result in the retention of salt and water. Inhibition of COX–derived PGs that contribute to the regulation of renal medullary blood flow may lead to a rise in blood pressure, increasing the risk of cardiovascular thrombotic events and heart failure. NSAIDs promote reabsorption of K as a result of decreased availability of Na at distal tubular sites and suppression of the PG–induced secretion of renin. The last effect may account in part for the usefulness of NSAIDs in the treatment of Barter syndrome (see Barter Syndrome section).

#### Analgesic Nephropathy

Analgesic nephropathy is a condition of slowly progressive renal failure, decreased concentrating capacity of the renal tubule, and sterile pyuria. Risk factors are the chronic use of high doses of combinations of NSAIDs and frequent urinary tract infections. If recognized early, discontinuation of NSAIDs may permit recovery of renal function.

#### Pregnancy

Myometrial COX-2 expression and levels of PGE, and PGF increase markedly in the myometrium during labor. Prolongation of gestation by NSAIDs has been demonstrated in humans. Some NSAIDs, particularly indomethacin, have been used off label to stop preterm labor. However, this use is associated with closure of the ductus arteriosus and impaired fetal circulation in utero, particularly in fetuses older than 32 weeks of gestation. COX-2–selective inhibitors have been used off label as tocolytic agents; this use has been associated with stenosis of the ductus arteriosus and oligohydramnios. Low-dose aspirin (81 mg/d) reduces the risk of preeclampsia by 24% when used as (off-label) preventive medication after 12 weeks of gestation in women who are at high risk (LeFevre and Force, 2014).

#### Hypersensitivity

Hypersensitivity symptoms to aspirin and NSAIDs range from vasomotor rhinitis, generalized urticaria, and bronchial asthma to laryngeal edema, bronchoconstriction, flushing, hypotension, and shock. Aspirin intolerance (including aspirin–associated asthma) is a contraindication to therapy with any other NSAID because of cross sensitivity. Although less common in children, this cross sensitivity may occur in 10%–25% of patients with asthma, nasal polyps, or chronic urticaria and in 1% of apparently healthy individuals. It is provoked by low doses (<80 mg) of aspirin and apparently involves COX inhibition. Treatment of aspirin hypersensitivity is similar to that of other severe hypersensitivity reactions, with support of vital organ function and administration of epinephrine.

#### Aspirin Resistance

All forms of treatment failure with aspirin have been collectively called aspirin resistance, but pharmacological resistance to aspirin is rare. Pseudoresistance, reflecting delayed and reduced drug absorption, complicates enteric-coated, but not immediate-release aspirin administration (Grosser et al., 2013).

#### Hepatotoxicity

Liver injury occurs in 17% of adults with unintentional acetaminophen overdose (Blieden et al., 2014). Liver toxicity from therapeutic doses of acetaminophen is extremely rare (see Acetaminophen section). By contrast, therapeutic dosing of diclofenac may be complicated by hepatotoxicity.
While the entire class of NSAIDs has a rate of less than 1 liver injury per 100,000 patients on average, chronic consumption of diclofenac is associated with a risk of 6–11 liver injuries per 100,000 users (Björnsson et al., 2013; de Abajo et al., 2004) (see Diclofenac section). NSAIDs are not recommended in advanced hepatic or renal disease.

**Reye Syndrome**

Due to the possible association with Reye syndrome, aspirin and other salicylates are contraindicated in children and young adults less than 20 years of age with viral illness–associated fever (Schrör, 2007). Reye syndrome, a severe and often fatal disease, is characterized by the acute onset of encephalopathy, liver dysfunction, and fatty infiltration of the liver and other viscera. Although a mechanistic understanding is lacking, the epidemiologic association between aspirin use and Reye syndrome is sufficiently strong that aspirin and bismuth subsalicylate labels must indicate the risk. As the use of aspirin in children has declined dramatically, so has the incidence of Reye syndrome. Acetaminophen and ibuprofen have not been implicated in Reye syndrome and are the agents of choice for antipyresis in children and youths.

**Drug Interactions**

Refer to the individual product labels for a comprehensive listing of NSAID drug-drug interactions.

**Concomitant NSAIDs and Low-Dose Aspirin**

Many patients consume both an NSAID for chronic pain and low-dose aspirin for cardioprevention. Epidemiological studies suggest that this combination therapy increases significantly the likelihood of GI adverse events over either class of NSAID alone. In addition, prior occupancy of platelet COX-1 by the NSAID can impede access of aspirin to its acetylation target Ser 529 and prevents irreversible inhibition of platelet function (Catella-Lawson et al., 2001). This has been unequivocally shown to occur with ibuprofen and naproxen and may also affect other isoform nonselective NSAIDs (Li et al., 2014). This drug-drug interaction may undermine the cardioprotective effect of aspirin. Celecoxib is unlikely to cause this drug-drug interaction in vivo, but confers a direct cardiovascular hazard (Grosser et al., 2017). Thus, pain management in patients with preexisting cardiovascular disease remains a particular challenge because of the cardiovascular adverse effects of NSAIDs and the risk of drug-drug interactions that might undermine the antplatelet effects of aspirin.

**Other Drug-Drug Interactions**

The ACE inhibitors act, at least partly, by preventing the breakdown of kinins that stimulate PG production (see Figure 39–4). Thus, NSAIDs may attenuate the effectiveness of ACE inhibitors by blocking the production of vasodilator and natriuretic PGs. The combination of NSAIDs and ACE inhibitors also can produce marked hyperkalemia, leading to cardiac arrhythmia, especially in the elderly and in patients with hypertension, diabetes mellitus, or ischemic heart disease. Corticosteroids and selective serotonin reuptake inhibitors may increase the frequency or severity of GI complications when combined with NSAIDs. NSAIDs may augment the risk of bleeding in patients receiving warfarin both because almost all NSAIDs suppress normal platelet function temporarily during the dosing interval and because some NSAIDs also increase warfarin levels by interfering with its metabolism. Thus, concurrent administration should be avoided.

Many NSAIDs are highly bound to plasma proteins, so they may displace other drugs from their binding sites. Such interactions can occur in patients given salicylates or other NSAIDs together with warfarin, sulfonlurea hypoglycemic agents, or methotrexate; the dosage of such agents may require adjustment to prevent toxicity. Patients taking lithium should be monitored because NSAIDs, including aspirin, reduce the renal excretion of this drug and can lead to toxicity.

**Pediatric and Geriatric Use**

**Therapeutic Uses in Children**

Therapeutic uses for NSAIDs in children include fever (acetaminophen, ibuprofen); pain (acetaminophen, ibuprofen); postoperative pain (ketorolac injection [single-dose only]); inflammatory disorders, such as juvenile arthritis (celecoxib, etodolac, meloxicam, naproxen, oxaprozin, tolmetin) and Kawasaki disease (off-label high-dose aspirin); and relief of ocular itching due to seasonal allergic rhinitis and postoperative inflammation after cataract extraction (ketorolac ophthalmic solution).

**Kawasaki Disease.** Aspirin generally is avoided in pediatric populations due to its potential association with Reye syndrome (see Reye Syndrome). However, high doses of aspirin (~30–100 mg/kg/d) are used to treat children during the acute phase of Kawasaki disease, followed by low-dose antplatelet therapy in the subacute phase.

**Pharmacokinetics in Children**

The NSAID dosing recommendations frequently are based on extrapolation of pharmacokinetic data from adults or children older than 2 years, and there are often insufficient data for dose selection in younger infants. For example, the pharmacokinetics of the most commonly used NSAID in children, acetaminophen, differ substantially between the neonatal period and older children or adults. The systemic bioavailability of rectal acetaminophen formulations in neonates and preterm babies is higher than in older patients. Acetaminophen clearance is reduced in preterm neonates, probably due to their immature glucuronide conjugation system (sulfation is the principal route of biotransformation at this age). Therefore, acetaminophen dosing intervals need to be extended (8–12 h) or daily doses reduced to avoid accumulation and liver toxicity.

Aspirin elimination also is delayed in neonates and young infants compared to adults, raising the risk of accumulation. Disease also may affect NSAID disposition in children. For example, ibuprofen plasma concentrations are reduced and clearance increased (~80%) in children with cystic fibrosis. This is probably related to the GI and hepatic pathologies associated with this disease. Aspirin’s kinetics are markedly altered during the febrile phase of rheumatic fever or Kawasaki vasculitis. The reduction in serum albumin associated with these conditions causes an elevation of the free salicylate concentration, which may saturate renal excretion and result in salicylate accumulation to toxic levels. In addition to dose reduction, monitoring of the free drug may be warranted in these situations.

**Pharmacokinetics in the Elderly**

The clearance of many NSAIDs is reduced in the elderly due to changes in hepatic metabolism and creatinine clearance. NSAIDs with a long t1/2 and primarily oxidative metabolism (i.e., piroxicam, tenoxicam, celecoxib) have elevated plasma concentrations in elderly patients. For example, plasma concentrations after the same dose of celecoxib may rise up to 2-fold higher in patients older than 65 years than in patients younger than 50 years of age, warranting dose adjustment. The capacity of plasma albumin to bind drugs is diminished in older patients and may result in higher concentrations of unbound NSAIDs. For example, free naproxen concentrations are markedly increased in older patients, although total plasma concentrations essentially are unchanged, and the higher susceptibility of older patients to GI complications may be due in part to elevated total or free NSAID concentrations. Generally, it is advisable to start most NSAIDs at a low dosage in the elderly and increase the dosage only if the therapeutic efficacy is insufficient.

**Specific Properties of Individual NSAIDs**

General properties shared by NSAIDs were considered in the section, Nonsteroidal Anti-inflammatory Drugs. In this section, important characteristics of individual substances are discussed. NSAIDs are grouped by their chemical similarity, as in Figure 38–1.

**Aspirin and Other Salicylates**

The salicylates include aspirin, salicylic acid, methyl salicylate, diflunisal, salsalate (an unapproved marketed drug in the U.S.), olasalazine, sulfasalazine, balsalazide, choline magnesium trisalicylate (an unapproved marketed drug in the U.S.), magnesium salicylate, mesalamine, and salicylamide (a carbamazepine derivative of salicylic acid contained as an ingredient in some OTC combination pain relievers). Salicylic acid is so irritating
that it can only be used externally; therefore, the various derivatives of this acid have been synthesized for systemic use. For example, aspirin is the acetate ester of salicylic acid (ASA). Aspirin is a widely consumed analgesic, antipyretic, and anti-inflammatory agent. Because aspirin is so available, the possibility of misuse and serious toxicity is underappreciated, and it remains a cause of fatal poisoning in children.

**Mechanism of Action**

The effects of aspirin are largely caused by its capacity to acetylate proteins, as described in Reversible Cyclooxygenase Inhibition by Aspirin. Other salicylates generally act by virtue of their content of salicylic acid, which is a relatively weak inhibitor of the purified COX enzymes. Salicylic acid may also suppress inflammatory upregulation of COX-2 by interfering with transcription factor binding to the COX-2 promoter.

**ADME**

**Absorption.** Orally ingested salicylates are absorbed rapidly, partly from the stomach, but mostly from the upper small intestine. The peak plasma level is reached in about 1 h. The rate of absorption is determined by disintegration and dissolution rates of the tablets administered, the pH at the mucosal surface, and gastric emptying time. Even though salicylate is more ionized as the pH is increased, a rise in pH also increases the solubility of salicylate and thus dissolution of the tablets. The overall effect is to enhance absorption. The presence of food delays absorption of salicylates. Rectal absorption of salicylate usually is slower than oral absorption and is incomplete and inconsistent.

Salicylic acid is absorbed rapidly from the intact skin, especially when applied in oily liniments or ointments, and systemic poisoning has occurred from its application to large areas of skin. Methyl salicylate likewise is speedily absorbed when applied cutaneously; however, its GI absorption may be delayed many hours, making gastric lavage effective for removal even in poisonings that present late after oral ingestion.

Enteric coating delays and reduces the bioavailability of aspirin by roughly half and renders absorption more variable in the presence of food (Bogentoft et al., 1978), which is likely the cause of “pseudoresistance” to aspirin (see Aspirin Resistance).

**Distribution.** After absorption, salicylates are distributed throughout most body tissues and transcellular fluids, primarily by pH-dependent processes. Salicylates are transported actively out of the CSF across the choroid plexus. The drugs readily cross the placental barrier. Ingested aspirin mainly is absorbed as such, but some enters the systemic circulation as salicylic acid after hydrolysis by esterases in the GI mucosa and liver. Roughly 80%–90% of the salicylate in plasma is bound to proteins, especially albumin; the proportion of the total that is bound declines as plasma concentrations increase. Hypoalbuminemia, as may occur in rheumatoid arthritis, is associated with a proportionately higher level of free salicylate in the plasma. Salicylate competes with a variety of compounds for plasma protein-binding sites; these include thyroxine, triiodothyronine, penicillin, phenytoin, sulfipyrazone, bilirubin, uric acid, and other NSAIDs, such as naproxen. Aspirin is bound to a more limited extent; however, it acetylates human plasma albumin in vivo by reaction with the ε-amino group of lysine and may change the binding of other drugs to albumin. Aspirin also acetylates other plasma and tissue proteins, but there is no evidence that this contributes to clinical efficacy or adverse events.

**Metabolism and Excretion.** Aspirin is rapidly deacetylated to form salicylic acid by spontaneous hydrolysis or esterases located in the intestinal wall, red blood cells, and the liver. The three chief metabolic products are salicylic acid (the glycine conjugate), the ether or phenolic glucuronide, and the ester or acyl glucuronide. Salicylates and their metabolites are excreted in the urine. The excretion of free salicylates is variable and depends on the dose and the urinary pH. For example, the clearance of salicylate is about four times as great at pH 8 as at pH 6, and it is well above the glomerular filtration rate at pH 8. High rates of urine flow decrease tubular reabsorption, whereas the opposite is true in oliguria. The plasma t1/2 for aspirin is about 20 min, and for salicylate is 2–3 h at antiplatelet doses, rising to 12 h at usual anti-inflammatory doses. The t1/2 of salicylate may rise to 15–30 h at high therapeutic doses or when there is intoxication. This dose-dependent elimination is the result of the limited capacity of the liver to form salicylic acid and the phenolic glucuronide, resulting in a larger proportion of unchanged drug being excreted in the urine at higher doses. Salicylate metabolism shows high intersubject variability due to the variable contribution of different metabolic pathways. Women frequently exhibit higher plasma concentrations, perhaps due to lower intrinsic esterase activity and gender differences in hepatic metabolism.

Salicylate clearance is reduced and salicylate exposure is significantly increased in the elderly. The plasma concentration of salicylate is increased by conditions that decrease the glomerular filtration rate or reduce proximal tubule secretion, such as renal disease, or the presence of inhibitors that compete for the transport system (e.g., probenecid). In case of an overdose, hemodialysis and hemofiltration techniques remove salicylic acid effectively from the circulation.

**Monitoring of Plasma Salicylate Concentrations.** Aspirin is one of the NSAIDs for which plasma salicylate can provide a means to monitor therapy and toxicity. Intermittent analgesic-antipyretic doses of aspirin typically produce plasma aspirin levels of less than 20 μg/mL and plasma salicylate levels of less than 60 μg/mL. The daily ingestion of anti-inflammatory doses of 4–5 g of aspirin produces plasma salicylate levels in the range of 120–350 μg/mL. Optimal anti-inflammatory effects for patients with rheumatic diseases require plasma salicylate concentrations of 150–300 μg/mL. Significant adverse effects can be seen at levels greater than 300 μg/mL. At lower concentrations, the drug clearance is nearly constant (despite the fact that saturation of metabolic capacity is approached) because the fraction of drug that is free, and thus available for metabolism or excretion, increases as binding sites on plasma proteins are saturated. The total concentration of salicylate in plasma is therefore a relatively linear function of dose at lower concentrations. At higher concentrations, however, as metabolic pathways of disposition become saturated, small increments in dose can disproportionately increase plasma salicylate concentration. Failure to anticipate this phenomenon can lead to toxicity.

**Therapeutic Uses**

**Systemic Uses.** The analgesic-antipyretic dose of aspirin for adults is 325–1000 mg orally every 4–6 h. It is only rarely used for inflammatory diseases such as arthritis, spondyloarthropathies, and systemic lupus erythematosus; NSAIDs with a better GI safety profile are preferred. The anti-inflammatory doses of aspirin, as might be given in rheumatic fever, range from 4 to 8 g/d in divided doses. The maximum recommended daily dose of aspirin for adults and children 12 years or older is 4 g. The rectal administration of aspirin suppositories may be preferred in infants or when the oral route is unavailable. Aspirin suppresses clinical signs and improves tissue inflammation in acute rheumatic fever. Other salicylates available for systemic use include salulate (salicylsalicylic acid), magnesium salicylate, diflunisal, and a combination of choline salicylate and magnesium salicylate (choline magnesium trisalicylate).

**Diflunisal** is a difluorophenyl derivative of salicylic acid that is not converted to salicylic acid in vivo. It is a competitive inhibitor of COX and a potent anti-inflammatory drug but is largely devoid of antipyretic effects, perhaps because of poor penetration into the CNS. The drug has been used primarily as an analgesic in the treatment of osteoarthritis and musculoskeletal strains or sprains; in these circumstances, it is about three to four times more potent than aspirin. For rheumatoid arthritis or osteoarthritis, 250–1000 mg/d is administered in two divided doses; maintenance dosage should not exceed 1.5 g/d. Diflunisal may produce

fewer auditory side effects (see Ototoxic Effects) and appears to cause fewer and less-intense GI and antithrombotic effects than does aspirin.

**Local Uses.** Mesalamine (5-aminosalicylic acid) is a salicylate that is used for its local effects in the treatment of inflammatory bowel disease (see Figure 51–4). Oral formulations that deliver drug to the lower intestine are efficacious in the treatment of inflammatory bowel disease (in particular, ulcerative colitis). These preparations rely on pH-sensitive coatings and other delayed-release mechanisms such as linkage to another moiety to create a poorly absorbed parent compound that must be cleaved by bacteria in the colon to form the active drug. Mesalamine is available as a rectal enema (6-methoxy-2-naphthylacetic acid prodrug) for treatment of mild-to-moderate ulcerative colitis, proctitis, and proctocolitis. Because of this delayed-release mechanism, the dosage required is lower than with the parent drug. Metabolites, Glucuronide and sulfates (renal excretion 70%–85%), Protein binding, 99% $t_{1/2}$ 1.2–2 h (immediate-release tablets); 12 h (topical epomalaine patch). Metabolites, conjugates $t_{1/2}$, 19–26 h; 22–38 h (elderly). Mesalamine is available as a rectal enema (6-methoxy-2-naphthylacetic acid prodrug) for treatment of mild-to-moderate ulcerative colitis, proctitis, and proctocolitis. These preparations rely on pH-sensitive coatings and other delayed-release mechanisms such as linkage to another moiety to create a poorly absorbed parent compound that must be cleaved by bacteria in the colon to form the active drug. Mesalamine is available as a rectal enema for treatment of mild-to-moderate ulcerative colitis, proctitis, and proctocolitis. Because of this delayed-release mechanism, the dosage required is lower than with the parent drug. Mesalamine derivatives in clinical use include balsalazide, sulfasalazine, and olsalazine. Sulfasalazine (salicylazosulfapyridine) contains mesalamine linked covalently to sulfapyridine, and balsalazide contains mesalamine linked to the inert carrier molecule 4-aminobenzoic acid. Sulfasalazine and olsalazine have been used in the treatment of rheumatoid arthritis and ankylosing spondylitis. Some OTC medications to relieve indigestion and diarrhea agents contain bismuth subsalicylate and have the potential to cause salicylate intoxication, particularly in children.

The keratolytic action of free salicylic acid is employed for the local treatment of warts, corns, fungal infections, and certain types of eczematous dermatitis. After treatment with salicylic acid, tissue cells swell, soften, and desquamate. Methyl salicylate (oil of wintergreen) is a common ingredient of ointments and deep-heating liniments used in the management of musculoskeletal pain; it also is available in herbal medicines and as a flavoring agent. The cutaneous application of methyl salicylate can result in pharmacologically active, and even toxic, systemic salicylate concentrations and has been reported to increase prothrombin time in patients receiving warfarin.

### Adverse Effects and Toxicity

#### Respiration

Salicylates increase O$_2$ consumption and CO$_2$ production (especially in skeletal muscle) at anti-inflammatory doses, a result of uncoupling oxidative phosphorylation. The increased production of CO$_2$ stimulates respiration. Salicylates also stimulate the respiratory center directly in the medulla. Respiratory rate and depth increases, the Pco$_2$ falls, and respiratory alkalosis ensues.

#### Acid-Base and Electrolyte Balance and Renal Effects

Therapeutic doses of salicylate produce definite changes in the acid-base balance and electrolyte pattern. Compensation for the initial event, respiratory alkalosis, is achieved by increased renal excretion of bicarbonate, which is accompanied by increased Na$^+$ and K$^+$ excretion; plasma bicarbonate is thus lowered, and blood pH returns toward normal. This stage of compensatory renal acidosis was often seen in adults given intensive salicylate therapy before the development of safer alternatives. Today, it is an indicator of ensuing intoxication (see Salicylate Intoxication). Salicylates can cause retention of salt and water, as well as acute reduction of renal function in patients with congestive heart failure, renal disease, or hypovolemia. Although long-term use of salicylates alone rarely is associated with nephrotoxicity, the prolonged and excessive ingestion of analgesic mixtures containing salicylates in combination with other NSAIDs can produce papillary necrosis and interstitial nephritis (see Analgesic Nephropathy).

#### Cardiovascular Effects

Low-dose aspirin (≤100 mg daily) lowers cardiovascular risk and is recommended for the prevention of myocardial infarction and stroke in patients at elevated risk (see Cardioprotection section) (Patrono, 2015). At high therapeutic doses (≥3 g daily), salt and water retention can lead to an increase in circulating plasma volume and decreased hematocrit (via a dilutional effect). There is a tendency for the peripheral vessels to dilate because of a direct effect on vascular smooth muscle. Cardiac output and work are increased. Those with cardiac or compromised cardiac function may not have sufficient cardiac reserve to meet the increased demands, and congestive cardiac failure and pulmonary edema can occur. High doses of salicylates can produce non-cardiogenic pulmonary edema, particularly in older patients who ingest salicylates regularly over a prolonged period.

#### GI Effects

Ingestion of salicylates may result in epigastric distress, heartburn, dyspepsia, nausea, and vomiting. Salicylates also may cause erosive gastritis and GI ulceration and hemorrhage. These effects occur primarily with acetylated salicylates (i.e., aspirin). Because nonacetylated salicylates lack the ability to acetylate COX and thereby irreversibly inhibit its activity, they are weaker inhibitors than aspirin. Aspirin-induced gastric bleeding sometimes is painless and, if unrecognized, may lead to iron-deficiency anemia. The daily ingestion of anti-inflammatory doses of aspirin (3–4 g) results in an average fecal blood loss of between 3 and 8 mL/d, as compared with about 0.6 mL/d in untreated subjects. Gastroscopic examination of aspirin-treated subjects often reveals discrete ulcerative and hemorrhagic lesions of the gastric mucosa; in many cases, multiple hemorrhagic lesions with sharply demarcated areas of focal necrosis are observed.

#### Hepatic Effects

Salicylates can cause hepatic injury, usually after high doses that result in plasma salicylate concentrations greater than 150 μg/mL. The injury is not an acute effect; rather, the onset...
characteristically occurs over several months of high-dose treatment. The majority of cases occur in patients with connective tissue disorders. There usually are no symptoms, simply an increase in serum levels of hepatic transaminases, but some patients note right upper quadrant abdominal discomfort and tenderness. Overt jaundice is uncommon. The injury usually is reversible on discontinuation of salicylates. However, the use of salicylates is contraindicated in patients with chronic liver disease. Considerable evidence implicates the use of salicylates as an important factor in the severe hepatic injury and encephalopathy observed in Reye syndrome. Large doses of salicylates may cause hyperglycemia and glyco- suria and deplete liver and muscle glycogen.

**Uricosuric Effects.** The effects of salicylates on uric acid excretion are markedly dependent on dose. Low doses (1 or 2 g/d) may decrease urate excretion and elevate plasma urate concentrations; intermediate doses (2 or 3 g/d) usually do not alter urate excretion. Larger-than-recommended doses (>5 g/d) induce uricosuria and lower plasma urate levels; however, such large doses are tolerated poorly. Even small doses of salicylate can block the effects of probenecid and other uricosuric agents that decrease tubular reabsorption of uric acid.

**HematoLogic Effects.** Irreversible inhibition of platelet function underlies the cardioprotective effect of aspirin. If possible, aspirin therapy should be stopped at least 1 week before surgery; however, preoperative aspirin often is recommended prior to cardiovascular surgery and percu- taneous interventions. Patients with severe hepatic damage, hypoprothrombinemia, vitamin K deficiency, or hemophilia should avoid aspirin because the inhibition of platelet hemostasis can result in hemorrhage. Salicylates ordinarily do not alter the leukocyte or platelet count, the hematocrit, or the hemoglobin content. However, doses of 3–4 g/d mark- edly decrease plasma iron concentration and shorten erythrocyte survival time. Aspirin can cause a mild degree of hemolysis in individuals with a deficiency of G6PD.

**Endocrine Effects.** Long-term administration of salicylates decreases thyroidal uptake and clearance of iodine, but increases O2 consumption and the rate of disappearance of thyroxine and triiodothyronine from the circulation. These effects probably are caused by the competitive displacement by salicylate of thyroxine and triiodothyronine from transthyre tin and the thyroxine-binding globulin in plasma (see Chapter 43).

**Ototoxic Effects.** Hearing impairment, alterations of perceived sounds, and tinnitus commonly occur during high-dose salicylate therapy and are sometimes observed at low doses. Ototoxic symptoms are caused by increased labyrinthine pressure or an effect on the hair cells of the cochlea, perhaps secondary to vasoconstriction in the auditory microvasculature. Symptoms usually resolve within 2 or 3 days after withdrawal of the drug. As most competitive COX inhibitors are not associated with hearing loss or tinnitus, a direct effect of salicylic acid rather than suppression of PG synthesis is likely.

**Salicylates and Pregnancy.** Infants born to women who ingest salicylates for long periods may have significantly reduced birth weights. When administered during the third trimester, there also is an increase in perinatal mortality, anemia, antepartum and postpartum hemorrhage, prolonged gestation, and complicated deliveries; thus, its use during this period should be avoided. NSAIDs during the third trimester of preg- nancy also can cause premature closure of the ductus arteriosus and should be avoided.

**Local Irritant Effects.** Salicylic acid is irritating to skin and mucosa and destroys epithelial cells.

**Salicylate Intoxication.** Salicylate poisoning or serious intoxication most often occurs in children and sometimes is fatal. CNS effects, intense hyperpnea, and hyperpyrexia are prominent symptoms. Death has followed use of 10–30 g of sodium salicylate or aspirin in adults, but much larger amounts (130 g of aspirin in one case) have been ingested without a fatal outcome. The lethal dose of methyl salicylate (also known as oil of wintergreen, sweet birch oil, gaultheria oil, betula oil) is considerably less than that of sodium salicylate. As little as a 4 mL (4.7 g) of methyl salicylate may cause severe systemic toxicity in children. Mild chronic salicylate intoxication is called salicylism. When fully developed, the syndrome includes headache, dizziness, tinnitus, difficulty hearing, dim- ness of vision, mental confusion, lassitude, drowsiness, sweating, thirst, hyperventilation, nausea, vomiting, and occasionally diarrhea.

**Neurological Effects.** In high doses, salicylates have toxic effects on the CNS, consisting of stimulation (including convulsions) followed by depression. Confusion, dizziness, tinnitus, high-tone deafness, delirium, psychosis, stupor, and coma may occur. Salicylates induce nausea and vomiting, which result from stimulation of sites that are accessible from the CSF, probably in the medullary chemoreceptor trigger zone.

**Respiration.** The respiratory effects of salicylates contribute to the serious acid-base balance disturbances that characterize poisoning by this class of compounds. Salicylates stimulate respiration indirectly by uncoupling of oxidative phosphorylation and directly by stimulation of the respiratory center in the medulla (described previously). Uncoupling of oxidative phosphorylation also leads to excessive heat production, and salicylate toxicity is associated with hyperthermia, particularly in children. Prolonged exposure to high doses of salicylates leads to depression of the medulla, with central respiratory depression and circulatory collapse, secondary to vasomotor depression. Because enhanced CO2 production continues, respiratory acidosis ensues. Respiratory failure is the usual cause of death in fatal cases of salicylate poisoning. Elderly patients with chronic salicylate intoxication often develop noncardiogenic pulmonary edema, which is considered an indication for hemodialysis.

**Acid-Base Balance and Electrolytes.** High therapeutic doses of salicy- late are associated with a primary respiratory alkalosis and compensatory metabolic acidosis. The phase of primary respiratory alkalosis rarely is rec- ognized in children with salicylate toxicity. They usually present in a state of mixed respiratory and metabolic acidosis, characterized by a decrease in blood pH, a low plasma bicarbonate concentration, and normal or nearly normal plasma Pco2. Direct salicylate-induced depression of respiration prevents adequate respiratory hyperventilation to match the increased peripheral production of CO2. Consequently, plasma Pco2 increases and blood pH decreases. Because the concentration of bicarbonate in plasma already is low due to increased renal bicarbonate excretion, the acid-base status at this stage essentially is an uncompensated respiratory acidosis. Superimposed, however, is a true metabolic acidosis caused by accum-ulation of acids as a result of three processes. First, toxic concentrations of salicylates displace plasma bicarbonate. Second, vasomotor depression caused by toxic doses of salicylates impairs renal function, with conse- quent accumulation of sulfuric and phosphoric acids; renal failure can ensue. Third, salicylates in toxic doses may decrease aerobic metabolism as a result of inhibition of various enzymes. This derangement of carbo- hydrate metabolism leads to the accumulation of organic acids, especially pyruvic, lactic, and acetoacetic acids.

The same series of events also causes alterations of water and electrolyte balance. The low plasma Pco2 leads to decreased renal tubular reabsorp- tion of bicarbonate and increased renal excretion of Na+, K+, and water. Water also is lost by salicylate-induced sweating (especially in the presence of hyperthermia) and hyperventilation. Dehydration, which can be pro- found, particularly in children, rapidly occurs. Because more water than electrolyte is lost through the lungs and by sweating, the dehydration is associated with hypernatremia.

**Cardiovascular Effects.** Toxic doses of salicylates lead to an exaggera- tion of the unfavorable cardiovascular responses seen at high therapeutic doses, and central vasomotor paralysis occurs. Petechiae may be seen due to defective platelet function.

**Metabolic Effects.** Large doses of salicylates may cause hyperglycemia and glycosuria and deplete liver and muscle glycogen; these effects are partly explained by the release of epinephrine. Such doses also reduce aerobic metabolism of glucose, increase glucose-6-phosphatase activity, and promote the secretion of glucocorticoids. There is a greater risk of hypoglycemia and subsequent permanent brain injury in children. Salicy- lates in toxic doses cause a significant negative nitrogen balance, char- acterized by an aminoaciduria. Adreno cortical activation may contribute to the negative nitrogen balance by enhancing protein catabolism. Salicy- lates reduce lipogenesis by partially blocking the incorporation of acetate into fatty acids; they also inhibit epinephrine-stimulated lipolysis in fat cells.
Acetaminophen is well tolerated; however, overdosage—two-thirds of antacids, expectorants, cold and flu preparations, and sore throat treatments. Important adverse interactions of aspirin with warfarin, sulfonlureas, and methorexates were mentioned previously (in Drug Interactions). Other interactions of aspirin include the antagonism of spironolactone-induced natriuresis and the blockade of the active transport of penicillin from CSF to blood. Magnesium-aluminum hydroxide antacids can alkalize the urine enough to increase salicylic acid clearance significantly and reduce steady-state concentrations. Conversely, discontinuation of antacid therapy can increase plasma concentrations to toxic levels.

**Acetaminophen**

Acetaminophen (paracetamol; N-acetyl-p-aminophenol) is the active metabolite of phenacetin.

Acetaminophen raises the threshold to painful stimuli, thus exerting an analgesic effect against pain due to a variety of etiologies. Acetaminophen is available without a prescription and is used as a common household analgesic by children and adults. It also is available in fixed-dose combinations containing narcotic and nonnarcotic analgesics (including aspirin and other salicylates), barbiturates, caffeine, vascular headache remedies, sleep aids, toothache remedies, antihistamines, antitussives, decongestants, expectorants, cold and flu preparations, and sore throat treatments. Acetaminophen is well tolerated; however, overdosage—two-thirds of which are intentionally induced—can cause severe hepatic damage (see Management of Salicylate Overdose). Salicylate poisoning represents an acute medical emergency, and death may result despite maximal therapy. Monitoring of salicylate levels is a useful guide to therapy but must be used in conjunction with an assessment of the patient’s overall clinical condition, acid-base balance, formulation of salicylate ingested, timing, and dose. There is no specific antidote for salicylate poisoning.

**Mechanism of Action**

Acetaminophen has analgesic and antipyretic effects similar to those of aspirin, but only weak anti-inflammatory effects. It is a nonselective COX inhibitor, which acts at the peroxide site of the enzyme and is thus distinct among NSAIDs. The presence of high concentrations of peroxides, as occur at sites of inflammation, reduces its COX-inhibitory activity.

**ADME**

Oral acetaminophen has excellent bioavailability. Peak plasma concentrations occur within 30–60 min, and the $t_{1/2}$ in plasma is about 2 h. Acetaminophen is relatively uniformly distributed throughout most body fluids. Binding of the drug to plasma proteins is variable, but less than with other NSAIDs. Some 90%–100% of drug may be recovered in the urine within the first day at therapeutic dosing, primarily after hepatic conjugation with glucuronic acid (~60%), sulfuric acid (~35%), or cysteine (~3%); small amounts of hydroxylated and deacetylated metabolites also have been detected (see Table 38–2). Children have less capacity for glucuronidation of the drug than do adults. A small proportion of acetaminophen undergoes CYP-mediated N-hydroxylation to form NAPQI, a highly reactive intermediate. This metabolite normally reacts with sulfhydryl groups in GSH and thereby is rendered harmless. However, after ingestion of large doses of acetaminophen, the metabolite is formed in amounts sufficient to deplete hepatic GSH and contributes significantly to the toxic effects of overdose (see Acetaminophen Intoxication).

**Therapeutic Uses**

Acetaminophen is suitable for analgesic or antipyretic uses; it is particularly valuable for patients in whom aspirin is contraindicated (e.g., those with aspirin hypersensitivity, children with a febrile illness, patients with bleeding disorders). The conventional oral dose of acetaminophen is 325–650 mg every 4–6 h; total daily doses should not exceed 4 g (2 g/d for chronic alcoholics). Single doses for children 2–11 years old depend on age and weight (~10–15 mg/kg); no more than five doses should be administered in 24 h. An injectable preparation is available. Particular attention is warranted due to the availability of a wide variety of prescription and nonprescription multi-ingredient medications that represent potentially toxic overlapping sources of acetaminophen.

**Adverse Effects and Toxicity**

Acetaminophen usually is well tolerated. Therapeutic doses of acetaminophen have no clinically relevant effects on the cardiovascular and respiratory systems, platelets, or coagulation. The GI adverse effects are less common than with therapeutic doses of NSAIDs. Rash and other allergic reactions occur occasionally, but sometimes these are more serious and may be accompanied by drug fever and mucosal lesions. Patients who show hypersensitivity reactions to the salicylates only rarely exhibit sensitivity to acetaminophen. The most serious acute adverse effect of overdosage of acetaminophen is a potentially fatal hepatic necrosis (Graham et al., 2005). Hepatic injury with acetaminophen involves its conversion to the toxic metabolite NAPQI. The glucuronide and sulfate conjugation pathways become saturated, and increasing amounts undergo CYP-mediated N-hydroxylation to form NAPQI. This is eliminated rapidly by conjugation with GSH and then further metabolized to a mercapturic acid and excreted into the urine. In the setting of acetaminophen overdose, hepatocellular levels of GSH become depleted. The highly reactive NAPQI metabolite binds covalently to cell macromolecules, leading to dysfunction of enzymatic systems and structural and metabolic disarray. Furthermore, depletion of intracellular GSH renders the hepatocytes highly susceptible to oxidative stress and apoptosis. Renal tubular necrosis and hypoglycemic coma also may occur.

In adults, hepatotoxicity may occur after ingestion of a single dose of 10–15 g (150–250 mg/kg) of acetaminophen; doses of 20–25 g or more are potentially fatal. Conditions of CYP induction (e.g., heavy alcohol consumption) or GSH depletion (e.g., fasting or malnutrition) increase the susceptibility to hepatic injury, which has been documented, albeit uncommonly, with doses in the therapeutic range. Plasma transaminases become elevated, sometimes markedly so, beginning about 12–36 h after ingestion. Symptoms that occur during the first 2 days of acute poisoning by acetaminophen reflect gastric distress (e.g., nausea, abdominal pain, anorexia) and belie the potential seriousness of the intoxication. Clinical indications of hepatic damage manifest within 2–4 days of ingestion of toxic doses, with right subcostal pain, tender hepatomegaly, jaundice, and coagulopathy. Renal impairment or frank renal failure may occur. Liver enzyme abnormalities typically peak 72–96 h after ingestion. Biopsy of the liver reveals centrilobular necrosis with sparing of the perportal area. In nonfatal cases, the hepatic lesions are reversible over a period of weeks or months.

**Management of Acetaminophen Intoxication**

Severe liver damage occurs in 90% of patients with plasma concentrations of acetaminophen greater than 300 µg/mL at 4 h or 45 µg/mL at 15 h after the ingestion of the drug. Activated charcoal, if given within 4 h of ingestion, decreases acetaminophen absorption by 50%–90% and should be administered if the ingested dose is suspected to exceed 7.5 g. NAC is indicated for those at risk of hepatic injury: NAC functions by detoxifying NAPQI. It both repletes GSH stores and may conjugate directly with NAPQI by serving as a GSH substitute. In addition to NAC therapy, aggressive supportive
care is warranted. This includes management of hepatic and renal failure, if they occur, and intubation if the patient becomes obtunded. Hypoglycemia can result from liver failure, and plasma glucose should be monitored closely. Fulminant hepatic failure is an indication for liver transplantation.

**Acetic Acid Derivatives**

**Diclofenac**

Diclofenac, a phenylacetic acid derivative, is among the most commonly used NSAIDs in Europe. Diclofenac has analgesic, antipyretic, and anti-inflammatory activities. Its potency is substantially greater than that of other NSAIDs. Although it was not developed to be a COX-2 selective drug, the selectivity of diclofenac for COX-2 resembles that of celecoxib (see Figure 38–1).

**ADME.** Diclofenac displays rapid absorption, extensive protein binding, and a $t_{1/2}$ of 1–2 h (see Table 38–2). The short $t_{1/2}$ makes it necessary to give doses of diclofenac considerably higher than would be required to inhibit COX-2 fully at peak plasma concentrations to afford sustained COX inhibition throughout the dosing interval. Thus, both COX isoforms are inhibited for the first phase of the dosing interval. However, as plasma levels decrease, diclofenac behaves like a COX-2 inhibitor in the later phase of the dosing interval. There is a substantial first-pass effect, such that only about 50% of diclofenac is available systemically. The drug accumulates in synovial fluid after oral administration, which may explain why its duration of therapeutic effect is considerably longer than its plasma $t_{1/2}$. Diclofenac is metabolized in the liver by a member of the CYP2C subfamily to 4-hydroxydiclofenac, the principal metabolite, and other hydroxylated forms; after glucuronidation and sulfation, the metabolites are excreted in the urine (65%) and bile (35%).

**Therapeutic Uses.** Diclofenac is approved in the U.S. for the long-term symptomatic treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, pain, primary dysmenorrhea, and acute migraine. Multiple oral formulations are available, providing a range of release times; the usual daily oral dosage is 50–150 mg, given in several divided doses. For acute pain such as migraine, a powdered form for dissolution in water and a solution for intravenous injection are available. Diclofenac also is available in combination with misoprostol, a PGE analogue; this combination retains the efficacy of diclofenac while reducing the frequency of GI ulcers and erosions. A 1% topical gel, a topical solution, and a transdermal patch are available for short-term treatment of pain due to minor strains, sprains, and bruises. A 3% gel formulation is indicated for topical treatment of actinic keratosis. In addition, an ophthalmic solution of diclofenac is available for treatment of postoperative inflammation following cataract extraction and for the temporary relief of pain and photophobia in patients undergoing corneal refractive surgery.

**Adverse Effects.** Diclofenac produces side effects (particularly GI) in about 20% of patients. The incidence of serious GI adverse effects, hypertension, and myocardial infarction are similar to the COX-2–selective inhibitors (Cannon et al., 2006). Hypersensitivity reactions have occurred following topical application and systemic administration. Severe liver injury occurs in 6–11 per 100,000 regular users annually (Bjornsson et al., 2013; de Abajo et al., 2004). Elevation of hepatic transaminases in plasma by more than three times the upper normal limit, indicating significant liver damage, occurs in about 4% of patients (Rostom et al., 2005). Transaminases should be monitored during the first 8 weeks of therapy with diclofenac. Other untoward responses to diclofenac include CNS effects, rashes, fluid retention, edema, and renal function impairment. The drug is not recommended for children, nursing mothers, or pregnant women.

Diclofenac is extensively metabolized. One metabolite, 4'-hydroxy diclofenac, can form reactive benzoquinone imines (similar to acetaminophen's metabolite NAPQI) that deplete hepatic GSH. Another highly reactive metabolite, diclofenac acyl glucuronide, is primarily catalyzed by UGT2B7 (King et al., 2001). Genetic variation that causes higher catalytic activity of UGT2B7 is associated with an increased risk of hepatotoxicity among patients taking diclofenac (Daly et al., 2007).

**Indomethacin**

Indomethacin is a methylated indole derivative indicated for the treatment of moderate-to-severe rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis; acute gouty arthritis; and acute painful shoulder.

Although indomethacin is still used clinically, mainly as a steroid-sparing agent, toxicity and the availability of safer alternatives have limited its use.

Indomethacin is a potent nonselective inhibitor of the COXs. It also inhibits the motility of polymorphonuclear leukocytes, depresses the biosynthesis of mucopolysaccharides, and may have a direct, COX-independent vasconstrictor effect. Indomethacin has prominent anti-inflammatory and analgesic-antipyretic properties similar to those of the salicylates.

**ADME.** Oral indomethacin has excellent bioavailability. Peak concentrations occur 1–2 h after dosing (Table 38–2). The concentration of the drug in the CSF is low, but its concentration in synovial fluid is equal to that in plasma within 5 h of administration. There is enterohemoperiodal cycling of the indomethacin metabolites and probably of indomethacin itself. The $t_{1/2}$ in plasma is variable, perhaps because of enterohemoperiodal cycling, but averages about 2.5 h.

**Therapeutic Uses.** While indomethacin is estimated to be about 20 times more potent than aspirin, a high rate of intolerance limits its use. An intravenous formulation of indomethacin is approved for closure of persistent patent ductus arteriosus in premature infants. The regimen involves intravenous administration of 0.1–0.25 mg/kg every 12 h for three doses, with the course repeated one time if necessary. Successful closure can be expected in more than 70% of neonates treated. The principal limitation of treating neonates is renal toxicity, and therapy is interrupted if the output of urine falls significantly (<0.6 mL/kg/h). An injectable formulation of ibuprofen is an alternative for the treatment of patent ductus arteriosus.

**Adverse Effects.** A very high percentage (35%–50%) of patients receiving indomethacin experience adverse drug reactions. GI adverse events are common and can be fatal; elderly patients are at significantly greater risk. Diarrhea may occur and sometimes is associated with ulcerative lesions of the bowel. Acute pancreatitis has been reported, as have rare, but potentially fatal, cases of hepatitis. The most frequent CNS effect is severe frontal headache. Dizziness, vertigo, light-headedness, and mental confusion may occur. Seizures have been reported, as have severe depression, psychosis, hallucinations, and suicide. Caution is advised when administering indomethacin to elderly patients or to those with underlying epilepsy, psychiatric disorders, or Parkinson disease because they are at greater risk for the development of serious CNS adverse effects. Hematopoietic reactions include neutropenia, thrombocytopenia, and rarely aplastic anemia.

The total plasma concentration of indomethacin plus its inactive metabolites is increased by concurrent administration of probenecid. Indomethacin antagonizes the natriuretic and antihypertensive effects of furosemide and thiazide diuretics and blunts the antihypertensive effect of β receptor antagonists, AT1-receptor antagonists, and ACE inhibitors.

**Sulindac**

Sulindac is a congener of indomethacin. Sulindac is a prodrug whose anti-inflammatory activity resides in its sulfide metabolite, which is more than 500 times more potent than sulindac as an inhibitor of COX but less than half as potent as indomethacin (see Figure 38–1). ADME data are summarized in Table 38–2. Sulindac is used for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, painful shoulder, and gouty arthritis. Its analgesic and anti-inflammatory effects are comparable to those achieved with aspirin. The most common dosage for adults is 150–200 mg twice a day. Although the incidence of toxicity is lower than with indomethacin, adverse reactions to sulindac are common. The typical NSAID GI side effects are seen in nearly 20% of patients. CNS side effects as described for indomethacin are seen in 10% or fewer of patients. Rash occurs in (3%–9%) of patients, and pruritus occurs in 1%–3% of patients. Transient elevations of hepatic transaminases in plasma are less common. The same precautions that apply to other NSAIDs regarding patients at risk for GI toxicity, cardiovascular risk, and renal impairment also apply to sulindac.
**Etodolac**

Etodolac is an acetic acid derivative with some degree of COX-2 selectivity (see Table 38–2, Figure 38–1). A single oral dose (200–400 mg) of etodolac provides postoperative analgesia that lasts for 6–8 h. Etodolac also is effective in the treatment of osteoarthritis, rheumatoid arthritis, and mild-to-moderate pain, and the drug appears to be uricosuric. Sustained-release preparations are available. Etodolac is relatively well tolerated. About 5% of patients who have taken the drug for 1 year or less discontinue treatment because of GI side effects, rashes, and CNS effects.

**Tolmetin**

Tolmetin is approved for the treatment of osteoarthritis, rheumatoid arthritis, and juvenile rheumatoid arthritis and has been used in the treatment of ankylosing spondylitis. ADME and comparison to aspirin are in Table 38–2. Tolmetin recommended doses for adults (200–600 mg three times/d) are typically given with meals, milk, or antacids to lessen abdominal discomfort. However, peak plasma concentrations and bioavailability are reduced when the drug is taken with food. Side effects occur in 25%–40% of patients who take tolmetin. GI side effects are the most common (~15%), and gastric ulceration has been observed. CNS side effects similar to those seen with indomethacin and aspirin occur, but they are less common and less severe.

**Ketorolac**

Ketorolac is a potent analgesic but only a moderately effective anti-inflammatory drug. The use of ketorolac is limited to 5 days or less for acute pain and can be administered orally, intravenously, intramuscularly, or intranasally. Typical doses are 30–60 mg (intramuscular), 15–30 mg (intravenous), 10–20 mg (oral), and 31.5 mg (intranasal). Pediatric patients aged between 2 and 16 years may receive a single intramuscular (1 mg/kg up to 30 mg) or intravenous (0.5 mg/kg up to 15 mg) dose of ketorolac for severe acute pain. Ketorolac has a rapid onset of action and a short duration of action (see Table 38–2). It is widely used in postoperative patients, but it should not be used for routine obstetric analgesia. Topical (ophthalmic) ketorolac is approved for the treatment of seasonal allergic conjunctivitis and postoperative ocular inflammation. Ketorolac in a fixed-dose combination with phenylephrine is indicated as an irrigation during cataract or intraocular lens replacement surgery to maintain pupil size, prevent miosis, and reduce postoperative pain. Side effects of systemic ketorolac include somnolence (6%), dizziness (7%), headache (17%), GI pain (13%), dyspepsia (12%), nausea (12%), and pain at the site of injection (2%). Serious adverse GI, renal, bleeding, and hypersensitivity reactions to ketorolac may occur. Patients receiving greater than recommended doses or concomitant NSAID therapy, and the elderly, appear to be particularly at risk.

**Nabumetone**

Nabumetone is the prodrug of 6-methoxy-2-naphthylacetic acid. Nabumetone is approved for the treatment of rheumatoid arthritis and osteoarthritis. Its comparative pharmacokinetic properties are summarized in Table 38–2. Nabumetone is associated with crampy lower abdominal pain (12%) and diarrhea (14%). Other side effects include rash (3%–9%); headache (3%–9%); dizziness (3%–9%); heartbeat, tinnitus, and pruritus (3%–9%).

**Propionic Acid Derivatives**

The propionic acid derivatives ibuprofen, naproxen, flurbiprofen, fenoprofen, ketoprofen, and oxaprozin are available in the U.S. (see Table 38–3). Ibuprofen is the most commonly used NSAID in the U.S. and is available with or without a prescription. Naproxen, also available with or without a prescription, has a longer but variable t½. Oxaprozin also has a long t½ and may be given once daily.

**Mechanism of Action**

Propionic acid derivatives are nonselective COX inhibitors with the effects and side effects common to other NSAIDs. Some of the propionic acid derivatives, particularly naproxen, have inhibitory effects on leukocyte function, and some evidence suggests that naproxen may have slightly better efficacy with regard to analgesia and relief of morning stiffness. This suggestion of benefit accords with the longer t½ of naproxen in comparison to other propionic acid derivatives.

**Therapeutic Uses**

Propionic acid derivatives are approved for use in the symptomatic treatment of rheumatoid arthritis, juvenile arthritis, and osteoarthritis. Some also are approved for pain, ankylosing spondylitis, acute gouty arthritis, tendinitis, bursitis, headache, postoperative dental pain and swelling, and primary dysmenorrhea. These agents may be comparable in efficacy to aspirin for the control of the signs and symptoms of rheumatoid arthritis and osteoarthritis.

**Drug Interactions**

Ibuprofen and naproxen have been shown to interfere with the antiplatelet effects of aspirin (Catella-Lawson et al., 2001; Li et al., 2014). Propionic acid derivatives have not been shown to alter the pharmacokinetics of the oral hypoglycemic drugs or warfarin. Refer to the full product labeling for a comprehensive listing of other drug interactions.

**Ibuprofen**

ADME. Table 38–3 summarizes the comparative pharmacokinetics of ibuprofen. Ibuprofen is absorbed rapidly, bound avidly to protein, and undergoes hepatic metabolism (90% is metabolized to hydroxylate or carboxylate derivatives) and renal excretion of metabolites. The t½ is about 2 h. Slow equilibration with the synovial space means that its antiarthritic effects may persist after plasma levels decline. In experimental animals, ibuprofen and its metabolites readily cross the placenta.

**Therapeutic Uses.** Ibuprofen is supplied as tablets, chewable tablets, capsules, caplets, and gelcaps containing 50–600 mg; as oral drops; and as an oral suspension. An injectable formulation of ibuprofen is approved to close patent ductus arteriosus in premature infants. Solid oral dosage forms containing 200 mg or less are available without a prescription. Ibuprofen is licensed for marketing alone and in fixed-dose combinations with antihistamines, decongestants, famotidine, oxycodone, and hydrocodone. It is short acting, with a t½ of about 2 h. The usual dose for mild-to-moderate pain is 400 mg every 4–6 h as needed.

**Adverse Effects.** Ibuprofen is better tolerated than aspirin and indomethacin and has been used in patients with a history of GI intolerance to other NSAIDs. Nevertheless, 5%–15% of patients experience GI side effects. Less-frequent adverse effects of ibuprofen include rashes (3%–9%), thrombocytopenia (<1%), headache (1%–3%), dizziness (3%–9%), blurred vision (<1%), and, in a few cases, toxic amblyopia (<1%), fluid retention (1%–3%), and edema (1%–3%). Patients who develop ocular disturbances should discontinue the use of ibuprofen and have an opthalmic evaluation. Ibuprofen can be used occasionally by pregnant women; however, the concerns apply regarding third-trimester effects, including delay of parturition. Excretion into breast milk is thought to be minimal, so ibuprofen also can be used with caution by women who are breastfeeding.

**Naproxen**

Naproxen is supplied as tablets, delayed-release tablets, extended-release tablets, gelcaps, and caplets containing 200–500 mg of naproxen or naproxen sodium and as an oral suspension and suppositories. Solid oral dosage forms containing 200 mg or less are available without a prescription. Naproxen is licensed for marketing alone and in fixed-dose combinations with pseudoephedrine, diphenhydramine, esomeprazole, and sumatriptan; it is copackaged with lansoprazole. Naproxen is indicated for juvenile and rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, pain, primary dysmenorrhea, tendonitis, bursitis, and acute gout.

ADME. Naproxen is absorbed fully after oral administration. Naproxen also is absorbed rectally but more slowly than after oral administration. Naproxen is almost completely (99%) bound to plasma proteins after normal therapeutic doses. The t½ of naproxen in plasma is variable, 9 to 25 h. Age plays a role in the variability of the t½ because of the age-related decline in renal function (and consequently longer t½) (see Table 38–3). Low doses should be prescribed in the elderly. Naproxen is extensively metabolized in the liver. About 30% of the drug undergoes 6-desmethylation, and most of this metabolite, as well as naproxen...

(Continued)
itself, is excreted as the glucuronide or other conjugates. Metabolites of naproxen are excreted almost entirely in the urine. Naproxen crosses the placenta and appears in the milk of lactating women at about 1% of the maternal plasma concentration.

**Adverse Effects.** Although the best available data were consistent with the suggestion that naproxen is an NSAID that is not associated with an increase in myocardial infarction rate (Coxib and Traditional NSAID Trialsists’ Collaboration et al., 2013), the FDA in 2015, based on the advisory committee recommendations, has issued a warning that NSAIDs can cause heart attacks and strokes, and that there is inconclusive evidence regarding whether the particular risk of any NSAID is definitively higher or lower than another NSAID (https://www.fda.gov/Drugs/DrugSafety/ucm451800.htm).

About 1%–10% of patients taking naproxen experience GI adverse effects that include heartburn, abdominal pain, constipation, diarrhea, nausea, dyspepsia, and stomatitis. Adverse effects with naproxen occur at approximately the same frequency as with indomethacin and other NSAIDs (see Table 38–1). CNS side effects include drowsiness (3%–9%), headache (3%–9%), dizziness (59%), vertigo (<3%), and depression (<1%). Other common reactions include pruritus (3%–9%) and diaphoresis (<3%). Rare instances of jaundice, impairment of renal function, angioedema, thrombocytopenia, and agranulocytosis have been reported.

**Fenamates**

The fenamates (anthranilic acids) include mefenamic acid, meclofenamate, and flufenamic acid. The pharmacological properties of the fenamates are similar to those of typical NSAIDs, and therapeutically, they have no advantages over others in the class (see Table 38–3). Mefenamic acid and meclofenamate sodium are used in the short-term treatment of pain in soft-tissue injuries, dysmenorrhea, and rheumatoid and osteoarthritis. These drugs are not recommended for use in children or pregnant women. Roughly 5% of patients develop a reversible elevation of hepatic transaminases. Diarrhea, which may be severe and associated with steatorrhea and inflammation of the bowel, also is relatively common. Autoimmune hemolytic anemia is a relatively common. Autoimmune hemolytic anemia is a

**Enolic Acids (Oxicams)**

The oxamic derivate piroxicam is the nonselective COX inhibitor with the longest half-life. Meloxicam shows modest COX-2 selectivity comparable to celecoxib (see Figure 38–1) and was approved as a COX-2–selective NSAID in some countries. These agents are similar in efficacy to aspirin, indomethacin, or naproxen for the long-term treatment of rheumatoid arthritis or osteoarthritis. The main advantage suggested for these compounds is their long half-life, which permits once-a-day dosing (see comparative pharmacokinetic and dosing data in Table 38–4).

**Piroxicam**

Piroxicam may inhibit activation of neutrophils, apparently independently of its ability to inhibit COX; hence, additional modes of anti-inflammatory action have been proposed, including inhibition of proteoglycanase and collagenase in cartilage.

Piroxicam is approved for the treatment of rheumatoid arthritis and osteoarthritis. Due to its slow onset of action and delayed attainment of steady state, it is less suited for acute analgesia but has been used to treat acute gout.

**ADME.** The pharmacokinetics of piroxicam are described in Table 38–4. The usual daily dose is 20 mg. Piroxicam is absorbed completely after oral administration and undergoes enterohepatic recirculation. Estimates of the half-life in plasma have been variable; the average is about 50 h. Steady-state blood levels are reached in 7–12 days. Less than 5% of the drug is excreted into the urine unchanged. The major metabolic transformation in humans is hydroxylation of the pyridyl ring (predominantly by an isozyme of the CYP2C subfamily), and this inactive metabolite and its glucuronide conjugate account for about 60% of the drug excreted in the urine and feces.

**Adverse Effects.** Approximately 20% of patients experience side effects with piroxicam, and about 5% of patients discontinue use because of these effects. Piroxicam may be associated with more GI and serious skin reactions than other nonselective NSAIDs. In 2007, the European Medicines Agency reviewed the safety of orally administered piroxicam and concluded that its benefits outweigh its risks, but advised it should no longer considered a first-line agent or be used for the treatment of acute (short-term) pain and inflammation.

**Meloxicam**

Meloxicam is approved for use in osteoarthritis, rheumatoid arthritis, and juvenile rheumatoid arthritis. The recommended adult dose of meloxicam is 7.5–15 mg once daily. Meloxicam demonstrates some COX-2 selectivity (see Figure 38–1). There is significantly less gastric injury compared to piroxicam (20 mg/d) in subjects treated with 7.5 mg/d of meloxicam, but the advantage is lost with a dosage of 15 mg/d (Patoia et al., 1996).

**Purpose-Developed COX-2 Selective NSAIDs**

Selective inhibitors of COX-2 are molecules with side chains that fit within its hydrophobic pocket but are too large to block COX-1 with equally high affinity. Celecoxib is the only purposefully developed COX-2 inhibitor still approved in the U.S. (see its clinical pharmacokinetic properties and precautions in Table 38–4). As mentioned, other, older compounds (diclofenac, etodolac, meloxicam, nimesulide) have been retrospectively found to have a certain degree of selectivity for COX-2 (see Figure 38–1). Etoricoxib is approved in several countries, but restricted in its indications; rofecoxib, valdecoxib, and lumiracoxib were withdrawn worldwide because of the cardiovascular complications caused by suppression of cardioprotective COX-2–derived PGs, especially PGI2, and the unrestrained effects of endogenous stimuli, such as platelet COX-1–derived TxA2, on platelet activation, vascular proliferation and remodeling, hypertension, and atherogenesis. COX-2–selective NSAIDs should be avoided in patients prone to cardiovascular or cerebrovascular disease. While the purposefully developed COX-2 inhibitors have generally been shown to reduce severe GI complications when compared to isoflunonese selective compounds, none of the COX-2–selective NSAIDs has established superior efficacy.

Time to peak plasma drug concentration C1/2 is after a single dose. In general, food delays absorption but does not decrease peak concentration. The majority of NSAIDs undergo hepatic metabolism, and the metabolites are excreted in the urine. Major metabolites or disposal pathways are listed. Typical t1/2 is listed for therapeutic doses if t1/2 is much different with the toxic dose, this is also given. Typical adult oral doses are listed unless otherwise noted. Refer to the current product labeling for complete prescribing information, including current labeled pediatric indications.
metabolites in the urine and feces. The elimination Plasma proteins. Most is excreted as carboxylic acid and glucuronide of younger patients (≤55 years of age). Celecoxib is bound extensively to Adverse Effects.

Therapeutic Uses.

Celecoxib is used for the management of acute pain for the treatment of osteoarthritis, rheumatoid arthritis, juvenile rheumatoid arthritis, ankyllosing spondylitis, and primary dysmenorrhea. The recommended dose for treating osteoarthritis is 200 mg/d as a single dose or divided as two doses. In the treatment of rheumatoid arthritis, the recommended dose is 100–200 mg twice daily. Due to cardiovascular hazard, physicians are advised to use the lowest possible dose for the shortest possible duration.

Adverse Effects. Celecoxib confers a risk of myocardial infarction and stroke, and this appears to relate to dose and the underlying risk of cardiovascular disease. Effects attributed to inhibition of PG production in the kidney—hypertension and edema—occur with nonselective COX inhibitors and also with celecoxib. Selective COX-2 inhibitors lose their GI advantage over other NSAIDs alone when used in conjunction with aspirin. Chronic use of celecoxib may decrease bone mineral density, particularly in older male patients. There is some suggestion that celecoxib may slow fracture healing and tendon-to-bone healing.

Disease-Modifying Antirheumatic Drugs

Rheumatoid arthritis is an autoimmune disease that affects about 1% of the population. The pharmacological management of rheumatoid arthritis includes symptomatic relief through the use of NSAIDs. However, although they have anti-inflammatory effects, NSAIDs have minimal, if any, effect on progression of joint deformity. Disease-modifying antirheumatic drugs (DMARDs), on the other hand, reduce the disease activity of rheumatoid arthritis and retard the progression of arthritic tissue destruction. DMARDs include a diverse group of small-molecule nonbiological and biological agents (mainly antibodies or binding proteins), as summarized in Table 38–5.

Biological DMARDs remain reserved for patients with persistent moderate or high disease activity and indicators of poor prognosis. Therapy is tailored to the individual patient, and the use of these agents must be weighed against their potentially serious adverse effects. The combination of NSAIDs with these agents is common.

**Enolic acid derivatives**

**ADME.** The bioavailability of oral celecoxib is not known; peak plasma levels occur at 2–4 h after administration. The elderly (>65 years of age) may have up to 2-fold higher peak concentrations and AUC values than younger patients (<55 years of age). Celecoxib is bound extensively to plasma proteins. Most is excreted as carboxylic acid and glucuronide metabolites in the urine and feces. The elimination \( t_{1/2} \) is about 11 h. The drug commonly is given once or twice daily during chronic treatment. Plasma concentrations are increased in patients with mild and moderate hepatic impairment, requiring reduction in dose. Celecoxib is metabolized predominantly by CYP2C9 and inhibits CYP2D6. Clinical vigilance is necessary during coadministration of drugs that are known to inhibit CYP2C9 and drugs that are metabolized by CYP2D6.

**Therapeutic Uses.** Celecoxib is used for the management of acute pain for the treatment of osteoarthritis, rheumatoid arthritis, juvenile rheumatoid arthritis, ankylosing spondylitis, and primary dysmenorrhea. The recommended dose for treating osteoarthritis is 200 mg/d as a single dose or divided as two doses. In the treatment of rheumatoid arthritis, the recommended dose is 100–200 mg twice daily. Due to cardiovascular hazard, physicians are advised to use the lowest possible dose for the shortest possible duration.

**Adverse Effects.** Celecoxib confers a risk of myocardial infarction and stroke, and this appears to relate to dose and the underlying risk of cardiovascular disease. Effects attributed to inhibition of PG production in the kidney—hypertension and edema—occur with nonselective COX inhibitors and also with celecoxib. Selective COX-2 inhibitors lose their GI advantage over other NSAIDs alone when used in conjunction with aspirin. Chronic use of celecoxib may decrease bone mineral density, particularly in older male patients. There is some suggestion that celecoxib may slow fracture healing and tendon-to-bone healing.

**Etoricoxib**

Etoricoxib is a COX-2–selective inhibitor with selectivity second only to that of lumiracoxib (see Figure 38–1). Etoricoxib is incompletely (−80%) absorbed and has a long \( t_{1/2} \) of 20–26 h. It is extensively metabolized before excretion. Patients with hepatic impairment are prone to drug accumulation. Renal insufficiency does not affect drug clearance. Etoricoxib is used for symptomatic relief in the treatment of osteoarthritis, rheumatoid arthritis, and acute gouty arthritis, as well as for the short-term treatment of musculoskeletal pain, postoperative pain, and primary dysmenorrhea. The drug is associated with the increased risk of heart attack and stroke. Etoricoxib is not available in the U.S.
Gout results from the precipitation of urate crystals in the tissues and the subsequent inflammatory response. Acute gout usually causes painful distal monoarthritis and can cause joint destruction, subcutaneous deposits (tophi), and renal calculi and damage. Gout affects 3% of the adult population of Western countries.

The pathophysiology of gout is incompletely understood. Hyperuricemia, while a prerequisite, does not inevitably lead to gout. Uric acid, the end product of purine metabolism, is relatively insoluble compared to its hypoxanthine and xanthine precursors, and normal serum urate levels (~5 mg/dL, or 0.3 mM) approach the limit of solubility. In most patients with gout, hyperuricemia arises from underexcretion rather than overproduction of urate. Mutations of one of the renal URATs, URAT-1, are associated with hypouricemia. Urate tends to crystallize as monosodium urate in colder or more acidic conditions. Monosodium urate crystals activate monocytes/macrophages via the toll-like receptor pathway mounting an innate immune response. This results in the activation of the cryopyrin inflammasome, the secretion of cytokines, including IL-1β and TNF-α, endothelial activation, and attraction of neutrophils to the site of inflammation. Neutrophils secrete inflammatory mediators that lower the local pH and lead to further urate precipitation. The aims of treatment are to:

- decrease the symptoms of an acute attack;
- decrease the risk of recurrent attacks; and
- lower serum urate levels.

The following substances are available for these purposes:

- Drugs that relieve inflammation and pain (NSAIDs, colchicine, glucocorticoids)
- Drugs that prevent inflammatory responses to crystals (colchicine and NSAIDs)
- Drugs that act by inhibition of urate formation (e.g., allopurinol, febuxostat) or to augment urate excretion (probenecid)

The NSAIDs have been discussed previously. Glucocorticoids are discussed in Chapter 46. This section focuses on colchicine, allopurinol, febuxostat, pegloticase, rasburicase, and the uricosuric agents probenecid and benzbromarone. Some other drugs used off label to reduce uric acid levels or treat gout include losartan, fenofibrate, and canakinumab; in 2011, the FDA denied a license application for canakinumab, citing an unfavorable risk-versus-benefit safety profile.

Colchicine

Colchicine is one of the oldest available therapies for acute gout. Plant extracts containing colchicine were used for joint pain in the 6th century. Colchicine is considered second-line therapy because it has a narrow therapeutic window and a high rate of side effects, particularly at higher doses.

Mechanism of Action

Colchicine exerts a variety of pharmacological effects, but how these relate to its activity in gout is partially understood (Leung et al., 2015). It has antimitotic effects, arresting cell division in G1 by interfering with microtubule and spindle formation (an effect shared with vinca alkaloids). This effect is greatest on cells with rapid turnover (e.g., neutrophils, GI epithelium). Depolymerization of microtubules by colchicine reduces neutrophil recruitment to inflamed tissue and neutrophil adhesion. Colchicine may alter neutrophil motility and decreases the secretion of chemotactic factors and superoxide anions by activated neutrophils. Colchicine limits monosodium urate crystal–induced NALP3

**Pharmacotherapy of Gout**

Gout results from the precipitation of urate crystals in the tissues and the subsequent inflammatory response. Acute gout usually causes painful distal monoarthritis and can cause joint destruction, subcutaneous deposits (tophi), and renal calculi and damage. Gout affects 3% of the adult population of Western countries.

The pathophysiology of gout is incompletely understood. Hyperuricemia, while a prerequisite, does not inevitably lead to gout. Uric acid, the end product of purine metabolism, is relatively insoluble compared to its hypoxanthine and xanthine precursors, and normal serum urate levels (~5 mg/dL, or 0.3 mM) approach the limit of solubility. In most patients with gout, hyperuricemia arises from underexcretion rather than overproduction of urate. Mutations of one of the renal URATs, URAT-1, are associated with hypouricemia. Urate tends to crystallize as monosodium urate in colder or more acidic conditions. Monosodium urate crystals activate monocytes/macrophages via the toll-like receptor pathway mounting an innate immune response. This results in the activation of the cryopyrin inflammasome, the secretion of cytokines, including IL-1β and TNF-α, endothelial activation, and attraction of neutrophils to the site of inflammation. Neutrophils secrete inflammatory mediators that lower the local pH and lead to further urate precipitation. The aims of treatment are to:

- decrease the symptoms of an acute attack;
- decrease the risk of recurrent attacks; and
- lower serum urate levels.

The following substances are available for these purposes:

- Drugs that relieve inflammation and pain (NSAIDs, colchicine, glucocorticoids)
- Drugs that prevent inflammatory responses to crystals (colchicine and NSAIDs)
- Drugs that act by inhibition of urate formation (e.g., allopurinol, febuxostat) or to augment urate excretion (probenecid)

The NSAIDs have been discussed previously. Glucocorticoids are discussed in Chapter 46. This section focuses on colchicine, allopurinol, febuxostat, pegloticase, rasburicase, and the uricosuric agents probenecid and benzbromarone. Some other drugs used off label to reduce uric acid levels or treat gout include losartan, fenofibrate, and canakinumab; in 2011, the FDA denied a license application for canakinumab, citing an unfavorable risk-versus-benefit safety profile.

Colchicine

Colchicine is one of the oldest available therapies for acute gout. Plant extracts containing colchicine were used for joint pain in the 6th century. Colchicine is considered second-line therapy because it has a narrow therapeutic window and a high rate of side effects, particularly at higher doses.

Mechanism of Action

Colchicine exerts a variety of pharmacological effects, but how these relate to its activity in gout is partially understood (Leung et al., 2015). It has antimitotic effects, arresting cell division in G1 by interfering with microtubule and spindle formation (an effect shared with vinca alkaloids). This effect is greatest on cells with rapid turnover (e.g., neutrophils, GI epithelium). Depolymerization of microtubules by colchicine reduces neutrophil recruitment to inflamed tissue and neutrophil adhesion. Colchicine may alter neutrophil motility and decreases the secretion of chemotactic factors and superoxide anions by activated neutrophils. Colchicine limits monosodium urate crystal–induced NALP3
section iv inflammation, immunomodulation, and hematoPOIESis

inflammasome activation and subsequent formation of IL-1β and IL-18. This mechanism may explain its therapeutic activity in familial Mediterranean fever and other inflammatory diseases. Colchicine inhibits the release of histamine-containing granules from mast cells, the secretion of insulin from pancreatic β cells, and the movement of melain granules in melanophores.

Colchicine also exhibits a variety of other pharmacological effects. It lowers body temperature, increases the sensitivity to central depressants, depresses the respiratory center, enhances the response to sympathomimetic agents, constricts blood vessels, and induces hypertension by central vasomotor stimulation. It enhances GI activity by neurogenic stimulation, but depresses it by a direct effect, and alters neuromuscular function.

ADME
Absorption of oral colchicine is rapid but variable. Peak plasma concentrations occur 0.5–2 h after dosing. Food does not affect the rate or extent of colchicine absorption. In plasma, 39% of colchicine is protein bound, primarily to albumin. The formation of colchicine-tubulin complexes in many tissues contributes to its large volume of distribution. There is significant enterohepatic circulation. The exact metabolism of colchicine in humans is unknown, but in vitro studies indicated that it may undergo oxidative demethylation by CYP3A4; glucuronidation may also be involved. In healthy volunteers, 40%–65% of the total absorbed oral dose of colchicine is recovered unchanged in the urine. The kidney, liver, and spleen also contain high concentrations of colchicine, but it apparently is largely excluded from heart, skeletal muscle, and brain. Colchicine is a substrate of P-glycoprotein efflux. The plasma t1/2 of colchicine is about 31 h. The drug is contraindicated in patients with hepatic or renal impairment requiring concomitant therapy with CYP3A4 or P-glycoprotein inhibitors. Colchicine is not removed by hemodialysis.

Therapeutic Uses
The dosing regimen for colchicine must be individualized on the basis of age, renal and hepatic function, concomitant use of other medications, and disease severity. A minimum of 3 days, but preferably 7–14 days, should elapse between courses of gout treatment with colchicine to avoid cumulative toxicity. Patients with hepatic or renal disease and dialysis patients should receive reduced doses or less-frequent therapy. For elderly patients, adjust the dose for renal function. For those with cardiac, renal, hepatic, or GI disease, NSAIDs or glucocorticoids may be preferred.

Acute Gout. Colchicine dramatically relieves acute attacks of gout. It is effective in roughly two-thirds of patients if given within 24 h of attack onset. Pain, swelling, and redness abate within 12 h and are completely gone within 48–72 h. The regimen approved for adults recommends a total of two doses taken 1 h apart: 1.2 mg (2 tablets) at the first sign of a gout flare followed by 0.6 mg (1 tablet) 1 h later. Patients with severe renal or hepatic dysfunction and patients receiving dialysis should not receive repeat courses of therapy more frequently than every 2 weeks.

Prevention of Acute Gout. Colchicine is used in the prevention of recurrent gout, particularly in the early stages of antihyperuricemic therapy. The typical dose for prophylaxis in patients with normal renal and hepatic function is 0.6 mg taken orally 3 or 4 days/week for patients who have less than 1 attack per year, 0.6 mg daily for patients who have more than 1 attack per year, and 0.6 mg up to two times daily for patients who have severe attacks.

Adverse Effects
Exposure of the GI tract to large amounts of colchicine and its metabolites via enterohepatic circulation and the rapid rate of turnover of the GI mucosa may explain why the GI tract is particularly susceptible to colchicine toxicity. Nausea, vomiting, diarrhea, and abdominal pain are the most common untoward effects and the earliest signs of impending colchicine toxicity. Drug administration should be discontinued as soon as these symptoms occur. There is a latent period, which is not altered by dose, of several hours or more between the administration of the drug and the onset of symptoms. A dosing study demonstrated that one dose initially and a single additional dose after 1 h was much less toxic than the traditional hourly dosing regimen for acute gout flares. Acute intoxication causes hemorrhagic gastropathy.

Other serious side effects of colchicine therapy include myelosuppression, leukopenia, granulocytopenia, thrombocytopenia, aplastic anemia, and rhombomylolysis. Life-threatening toxicities are associated with administration of concomitant therapy with P-glycoprotein or CYP3A4 inhibitors. The FDA suspended the U.S. marketing of all injectable dosage forms of colchicine in 2008. Colchicine is marketed in a fixed-dose combination with probenecid for the management of frequent recurrent gout attacks.

Allopurinol
History
Allopurinol initially was synthesized as a candidate antineoplastic agent but was found to lack antineoplastic activity. Subsequent testing showed it to be an inhibitor of XO that was useful clinically for the treatment of gout.

Allopurinol inhibits XO and prevents the synthesis of urate from hypoxanthine and xanthine. Allopurinol is used to treat hyperuricemia in patients with gout and to prevent it in those with hematological malignancies about to undergo chemotherapy (acute tumor lysis syndrome). Even though underexcretion rather than overproduction is the underlying defect in most gout patients, allopurinol remains effective therapy.

Allopurinol is an analogue of hypoxanthine. Its active metabolite, oxipurinol, is an analogue of xanthine.

Mechanism of Action
Both allopurinol and its primary metabolite, oxipurinol (alloxanthine), reduce urate production by inhibiting XO, which converts xanthine to uric acid. Allopurinol competitively inhibits XO at low concentrations and is a noncompetitive inhibitor at high concentrations. Allopurinol also is a substrate for XO; the product of this reaction, oxipurinol, also is a noncompetitive inhibitor of the enzyme. The formation of oxipurinol, together with its long persistence in tissues, is responsible for much of the pharmacological activity of allopurinol.

In the absence of allopurinol, the dominant urinary purine is uric acid. During allopurinol treatment, the urinary purines include hypoxanthine, xanthine, and uric acid. Because each has its independent solubility, the concentration of uric acid in plasma is reduced and purine excretion is increased, without exposing the urinary tract to an excessive load of uric acid. Despite their increased concentrations during allopurinol therapy, hypoxanthine and xanthine are efficiently excreted, and tissue deposition does not occur. There is a small risk of xanthine stones in patients with a very high urate load before allopurinol therapy, which can be minimized by liberal fluid intake and urinary alkalinization.

Allopurinol facilitates the dissolution of tophi and prevents the development or progression of chronic gouty arthritis by lowering the uric acid concentration in plasma below the limit of its solubility. The formation of uric acid stones virtually disappears with therapy, which prevents the development of nephropathy. Once significant renal injury has occurred, allopurinol cannot restore renal function but may delay disease progression. The incidence of acute attacks of gouty arthritis may increase during the early months of allopurinol therapy as a consequence of mobilization of tissue stores of uric acid. Coadministration of colchicine helps suppress such acute attacks. In some patients, the allopurinol-induced increase in excretion of oxypurines is less than the reduction in uric acid excretion; this disparity primarily is a result of reutilization of oxypurines and feedback inhibition of de novo purine biosynthesis.
Allopurinol is contraindicated in patients who have exhibited serious adverse effects or hypersensitivity reactions to the medication and in nursing mothers and children, except those with malignancy or certain inborn errors of purine metabolism (e.g., Lesch-Nyhan syndrome). Allopurinol generally is used in patients with hyperuricemia posttransplantation. It can be used in conjunction with a uricosuric agent.

**Drug Interactions**

Allopurinol increases the $t_{1/2}$ of probenecid and enhances its uricosuric effect, while probenecid increases the clearance of oxypurinol, thereby increasing dose requirements of allopurinol. Allopurinol inhibits the enzymatic inactivation of mercaptopurine and its derivative azathioprine by XO. Thus, when allopurinol is used concomitantly with oral mercaptopurine or azathioprine, dosage of the antineoplastic agent must be reduced to 25%–33% of the usual dose (see Chapters 35 and 66). This is of importance when treating gout in the transplant recipient. The risk of bone marrow suppression also is increased when allopurinol is administered with cytotoxic agents that are not metabolized by XO, particularly cyclophosphamide. Allopurinol also may interfere with the hepatic inactivation of other drugs, including warfarin. Although the effect is variable, increased monitoring of prothrombin activity is recommended in patients receiving both medications.

It remains to be established whether the increased incidence of rash in patients receiving concurrent allopurinol and ampicillin should be ascribed to allopurinol or to hyperuricemia. Hypersensitivity reactions have been reported in patients with compromised renal function, especially those who are receiving a combination of allopurinol and a thiazide diuretic. The concomitant administration of allopurinol and theophylline leads to increased accumulation of an active metabolite of theophylline, 1-methylxanthine; the concentration of theophylline in plasma also may be increased (see Chapter 40).

**Febuxostat**

Febuxostat is a nonpurine inhibitor of XO. Unlike oxypurinol, the active metabolite of allopurinol, which inhibits the reduced form of XO, febuxostat forms a stable complex with both the reduced and oxidized enzymes and inhibits catalytic function in both states.

**ADME**

Febuxostat is rapidly absorbed with maximum plasma concentrations at 1–1.5 h postdose. The absolute bioavailability is unknown. Magnesium hydroxide and aluminum hydroxide delay absorption by about 1 h. Food reduces absorption slightly. Febuxostat, $t_{1/2}$ of 5–8 h, is extensively metabolized by both conjugation via UGT enzymes, including UGT1A1, UGT1A3, UGT1A9, and UGT2B7, and oxidation by CYPs 1A2, 2C8, and 2C9 and non-CYP enzymes and has elimination that is dependent on hepatic and renal pathways. Mild-to-moderate renal or hepatic impairment does not affect its elimination kinetics relevantly.

**Therapeutic Use**

Febuxostat is approved for hyperuric patients with gout attacks but is not recommended for treatment of asymptomatic hyperuricemia. It is available in 40- and 80-mg oral tablets. A dose of 40-mg/d febuxostat lowered serum uric acid to similar levels as 300-mg/d allopurinol. More patients reached the target concentration of 6.0 mg/dL (360 μmol/L) on 80-mg/d febuxostat than on 300-mg/d allopurinol. Thus, therapy should be initiated with 40 mg/d and the dose increased if the target serum uric acid concentration is not reached within 2 weeks.

**Adverse Events**

The most common adverse reactions in clinical studies were liver function abnormalities, nausea, joint pain, and rash. Liver function should be monitored periodically. An increase in gout flares was frequently observed after initiation of therapy, due to reduction in serum uric acid levels resulting

**Therapeutic Uses**

Febuxostat is an XO inhibitor approved for treatment of hyperuricemia in patients with gout.

**Mechanism of Action**

Febuxostat is a nonpurine inhibitor of XO. Unlike oxypurinol, the active metabolite of allopurinol, which inhibits the reduced form of XO, febuxostat forms a stable complex with both the reduced and oxidized enzymes and inhibits catalytic function in both states.

**ADME**

Febuxostat is rapidly absorbed with maximum plasma concentrations at 1–1.5 h postdose. The absolute bioavailability is unknown. Magnesium hydroxide and aluminum hydroxide delay absorption by about 1 h. Food reduces absorption slightly. Febuxostat, $t_{1/2}$ of 5–8 h, is extensively metabolized by both conjugation via UGT enzymes, including UGT1A1, UGT1A3, UGT1A9, and UGT2B7, and oxidation by CYPs 1A2, 2C8, and 2C9 and non-CYP enzymes and has elimination that is dependent on hepatic and renal pathways. Mild-to-moderate renal or hepatic impairment does not affect its elimination kinetics relevantly.

**Therapeutic Use**

Febuxostat is approved for hyperuric patients with gout attacks but is not recommended for treatment of asymptomatic hyperuricemia. It is available in 40- and 80-mg oral tablets. A dose of 40-mg/d febuxostat lowered serum uric acid to similar levels as 300-mg/d allopurinol. More patients reached the target concentration of 6.0 mg/dL (360 μmol/L) on 80-mg/d febuxostat than on 300-mg/d allopurinol. Thus, therapy should be initiated with 40 mg/d and the dose increased if the target serum uric acid concentration is not reached within 2 weeks.

**Adverse Events**

The most common adverse reactions in clinical studies were liver function abnormalities, nausea, joint pain, and rash. Liver function should be monitored periodically. An increase in gout flares was frequently observed after initiation of therapy, due to reduction in serum uric acid levels resulting in patients receiving concurrent allopurinol and ampicillin should be ascribed to allopurinol or to hyperuricemia. Hypersensitivity reactions have been reported in patients with compromised renal function, especially those who are receiving a combination of allopurinol and a thiazide diuretic. The concomitant administration of allopurinol and theophylline leads to increased accumulation of an active metabolite of theophylline, 1-methylxanthine; the concentration of theophylline in plasma also may be increased (see Chapter 40).

**Febuxostat**

Febuxostat is an XO inhibitor approved for treatment of hyperuricemia in patients with gout.

**Mechanism of Action**

Febuxostat is a nonpurine inhibitor of XO. Unlike oxypurinol, the active metabolite of allopurinol, which inhibits the reduced form of XO, febuxostat forms a stable complex with both the reduced and oxidized enzymes and inhibits catalytic function in both states.

**ADME**

Febuxostat is rapidly absorbed with maximum plasma concentrations at 1–1.5 h postdose. The absolute bioavailability is unknown. Magnesium hydroxide and aluminum hydroxide delay absorption by about 1 h. Food reduces absorption slightly. Febuxostat, $t_{1/2}$ of 5–8 h, is extensively metabolized by both conjugation via UGT enzymes, including UGT1A1, UGT1A3, UGT1A9, and UGT2B7, and oxidation by CYPs 1A2, 2C8, and 2C9 and non-CYP enzymes and has elimination that is dependent on hepatic and renal pathways. Mild-to-moderate renal or hepatic impairment does not affect its elimination kinetics relevantly.
in mobilization of urate from tissue deposits. Concurrent prophylactic treatment with an NSAID or colchicine is usually required. There was a higher rate of myocardial infarction and stroke in patients on febuxostat than on allopurinol. Whether there is a causal relationship between the cardiovascular events and febuxostat therapy or whether these were due to chance is not clear. Meanwhile patients should be monitored for cardiovascular complications.

**Drug Interactions**

Plasma levels of drugs metabolized by XO (e.g., theophylline, mercaptourine, azathioprine) will increase when administered concurrently with febuxostat. Thus, febuxostat is contraindicated in patients on azathioprine or mercaptopurine; care should be exercised with concomitant administration of theophylline due to a 400-fold increase in the urinary excretion of the 1-methylxanthine metabolite.

**Uricase**

Pegloticase is a pegylated uricase (urate oxidase) that catalyzes the enzymatic oxidation of uric acid into allantoin, a more soluble and inactive derivative. Pegloticase, a recombinant enzyme, based on the porcine uricase, is administered by infusion. Pegloticase is used for the treatment of severe, treatment-refractory, chronic gout or when use of other urate-lowering therapies is contraindicated.

The drug’s efficacy may be hampered by the production of antibodies against the drug. Pegloticase antibodies develop in nearly 90% of people, and high titers are associated with loss of the urate-lowering effect and with an elevated risk for infusion reactions. Anaphylactic reactions, and hemolysis in G6PD-deficient patients, have been associated with the use of pegloticase. Other frequently observed adverse reactions include vomiting, nausea, chest pain, constipation, diarrhea, and urticaria.

Rasburicase is a recombinant uricase that has been shown to lower urate levels more effectively than allopurinol. It is indicated for the initial management of elevated plasma uric acid levels in pediatric and adult patients with leukemia, lymphoma, and solid tumor malignancies who are receiving anticancer therapy expected to result in tumor lysis and significant hyperuricemia. The experience with rasburicase for treatment of gout is limited because of the formation of activity-limiting antibodies against the drug. Hemolysis in G6PD-deficient patients, methemoglobinemia, acute renal failure, and anaphylaxis have been associated with the use of rasburicase. Other frequently observed adverse reactions include vomiting, fever, nausea, headache, abdominal pain, constipation, diarrhea, and mucositis. Rasburicase causes enzymatic degradation of the uric acid in blood samples, and special handling is required to prevent spuriously low values for plasma uric acid in patients receiving the drug.

**Uricosuric Agents**

Uricosuric agents increase the excretion of uric acid. These agents are typically reserved for patients who underexcrete uric acid relative to their plasma levels. In humans, urate is filtered, secreted, and reabsorbed by the kidneys. Reabsorption is robust, such that the net amount excreted usually is about 10% of that filtered. Reabsorption is mediated by an OAT family member, URAT-1, which can be inhibited.

Urate is exchanged by URAT-1 for either an organic anion such as lactate or nicotinate or less potently for an inorganic anion such as chloride. Uricosuric drugs such as probenecid, benzbramorone (not available in the U.S.), and losartan compete with urate for the transporter, thereby inhibiting its reabsorption via the urate–anion exchanger system. However, transport is bidirectional, and depending on dosage, a drug may either decrease or increase the excretion of uric acid.

There are two mechanisms by which a drug may nullify the uricosuric action of another. First, the drug may inhibit the secretion of the uricosuric agent, thereby denying it access to its site of action, the luminal aspect of the brush border. Second, the inhibition of urate secretion by one drug may counterbalance the inhibition of urate reabsorption by the other.

**Mechanism of Action. Inhibition of Organic Acid Transport.** The actions of probenecid are confined largely to inhibition of the transport of organic acids across epithelial barriers. Probenecid inhibits the reabsorption of uric acid by OATs, principally URAT-1. Uric acid is the only important endogenous compound whose excretion is known to be increased by probenecid. The uricosuric action of probenecid is blunted by the coadministration of salicylates.

**Inhibition of Transport of Miscellaneous Substances.** Probenecid inhibits the tubular secretion of a number of drugs, such as methotrexate and the active metabolite of clofibrate. It inhibits renal secretion of the inactive glucuronide metabolites of NSAIDs such as naproxen, ketoprofen, and indomethacin and thereby can increase their plasma concentrations. Probenecid inhibits the transport of 5-HIAA and other acidic metabolites of cerebral monoamines from the CSF to the plasma. The transport of drugs such as penicillin G also may be affected, and probenecid is used therapeutically to elevate and prolong plasma β-lactam levels. Probenecid depresses the biliary secretion of certain compounds, including the diagnostic agents indocyanine green and bromosulphophthalein. It also decreases the biliary secretion of rifampin, leading to higher plasma concentrations.

**ADME.** Probenecid is absorbed completely after oral administration. Peak plasma concentrations are reached in 2–4 h. The t1/2 of the drug in plasma is dose dependent and varies from less than 5 to more than 8 h. Between 85% and 95% of the drug is bound to plasma albumin; the 5%–15% of unbound drug is cleared by glomerular filtration and active secretion by the proximal tubule. A small amount of probenecid glucuronide appears in the urine. It also is hydroxylated to metabolites that retain their carboxyl function and have uricosuric activity.

**Therapeutic Uses.** Probenecid is marketed for oral administration, alone and in combination with colchicine. The starting dose is 250 mg twice daily, increasing over 1–2 weeks to 500–1000 mg twice daily. Probenecid increases urinary urate levels. Liberal fluid intake therefore should be maintained throughout therapy to minimize the risk of renal stones. Probenecid should not be used in gouty patients with nephrolithiasis or with overproduction of uric acid. Concomitant colchicine or NSAIDs are indicated early in the course of therapy to avoid precipitating an attack of gout, which may occur in 20% or fewer of gouty patients treated with probenecid alone. After 6 months, if serum uric acid levels are within normal limits and there have been no gout attacks, the dose of probenecid may be tapered off by 500 mg every 6 months.

**Combination With Penicillin.** Higher doses of probenecid (1–2 g/d) are used as an adjuvant to prolong the dwell time of penicillin and other β-lactam antibiotics in the body (see Chapter 57).

**Adverse Effects.** Probenecid is well tolerated. Approximately 2% of patients develop mild GI irritation. The risk is increased at higher doses. It is ineffective in patients with renal insufficiency and should be avoided in those with creatinine clearance of less than 30 mL/min. Hypersensitivity reactions usually are mild and occur in 2%–4% of patients. Substantial overdosage with probenecid results in CNS stimulation, convulsions, and death from respiratory failure.

**Benzbromarone**

Benzbromarone is a potent uricosuric agent that has been marketed in several countries since 1970. It is a reversible inhibitor of the urate–anion exchanger in the proximal tubule. Hepatotoxicity reported in conjunction with its use has limited its availability. The drug is absorbed readily after oral ingestion; peak plasma levels are achieved in about 4 h. It is
Lesinurad
Lesinurad is FDA approved for combination therapy with an XO inhibitor in treating hyperuricemia.

Mechanism of Action. Lesinurad inhibits the URAT-1 and OAT-4 transporters, thereby reducing renal uric acid reabsorption.

ADME. Lesinurad is rapidly absorbed after oral administration and has bioavailability of about 100%. Lesinurad is largely bound to plasma albumin and other plasma proteins (~98%). The elimination t1/2 is about 5 h. The pharmacokinetics of Lesinurad are linear over the dose range of 25 to 100 mg. It is effective in patients with renal insufficiency and may be prescribed to patients who are either allergic or refractory to other drugs used for the treatment of gout. Preparations that combine allopurinol and benzbromarone are more effective than either drug alone in lowering serum uric acid levels, in spite of the fact that benzbromarone lowers plasma levels of oxypurinol, the active metabolite of allopurinol. The uricosuric action is blunted by aspirin or sulfinpyrazone.

Lesinurad is FDA approved for combination therapy with an XO inhibitor in treating hyperuricemia.

Therapeutic Uses. Lesinurad (200 mg/d) is marketed for the treatment of gout in patients who have not achieved the target serum uric acid levels with an XO inhibitor alone. It should not be used for the treatment of asymptomatic hyperuricemia or as monotherapy.

Adverse Effects. Lesinurad has been labeled with a black-box warning because of a risk of acute renal failure that is more common when it is used without an XO inhibitor. Increases in blood creatinine levels (1.5- to 2-fold) were observed with a frequency of approximately 4% during combination therapy and 8% during monotherapy. Renal failure occurred in less than 1% of patients during combination therapy and approximately 9% during monotherapy. Similarly, the risk of nephrothiasis is increased when lesinurad is given alone. Thus, if treatment with the XO inhibitor is interrupted, lesinurid dosing should also be interrupted. Other adverse reactions reported by patients during clinical trials include headache (~5%), influenza-like symptoms (~5%), and gastroesophageal reflux (~3%).

- Kinin Receptor Antagonists

Endogenous histamine plays a role in the immediate allergic response and is an important regulator of gastric acid secretion. More recently, a role for histamine as a modulator of neurotransmitter release in the central and peripheral nervous systems has emerged. The cloning of four receptors for histamine and the development of subtype-specific receptor antagonists have enhanced our understanding of the physiological and pathophysiological roles of histamine. Competitive antagonists of \( \text{H}_1 \) receptors are used therapeutically in treating allergies, urticaria, anaphylactic reactions, nausea, motion sickness, and insomnia. Antagonists of the \( \text{H}_2 \) receptor are effective in reducing gastric acid secretion.

The peptides bradykinin and kallidin, released after activation of the kallikrein-kinin system, have cardiovascular effects similar to those of histamine and play prominent roles in inflammation and nociception. Icatibant, a competitive antagonist of the bradykinin \( \text{B}_2 \) receptor, and ecallantide, a specific plasma kallikrein inhibitor, are approved for the treatment of acute episodes of edema in patients with hereditary angioedema.

Histamine

Histamine is a hydrophilic molecule consisting of an imidazole ring and an amino group connected by an ethylene group; histamine is biosynthesized from histidine by decarboxylation (Figure 39–1). Histamine acts through four classes of receptors, designated \( \text{H}_1 \) through \( \text{H}_4 \). The four histamine receptors, all GPCRs, can be differentially activated by analogues of histamine (Figure 39–2) and inhibited by specific antagonists (Table 39–1).

Distribution and Biosynthesis

Distribution

Almost all mammalian tissues contain histamine in amounts ranging from less than 1 to more than 100 μg/g. Concentrations in plasma and other body fluids are generally very low, but they are significant in human CSF.

Synthesis, Storage, and Metabolism

Histamine is formed by the decarboxylation of histidine by the enzyme \( \text{L-histidine decarboxylase} \) (Figure 39–1). Mast cells and basophils synthesize histamine and store it in secretory granules. At the secretory granule pH of about 5.5, histamine is positively charged and ionically complexed with negatively charged acidic groups on other granule constituents, primarily proteases and heparin or chondroitin sulfate proteoglycans. The turnover rate of histamine in secretory granules is slow (days to weeks). Non–mast cell sites of histamine formation include the epidermis, enterochromaffin-like cells of the gastric mucosa, neurons within the CNS, and cells in regenerating or rapidly growing tissues. Turnover is rapid at these non–mast cell sites because the histamine is released continuously rather than stored. Non–mast cell sites of histamine production contribute significantly to the daily excretion of histamine metabolites in the urine. Because \( \text{L-histidine decarboxylase} \) is an inducible enzyme, the histamine-forming capacity at such sites is subject to regulation. Histamine that is released or ingested is rapidly metabolized by either ring methylation catalyzed by \( \text{histamine-N-methyltransferase} \) or oxidative deamination catalyzed by \( \text{diamine oxidase} \) (Figure 39–1), and the metabolites are eliminated in the urine.

Release and Functions of Endogenous Histamine

Histamine is released from storage granules as a result of the interaction of antigen with IgE antibodies on the mast cell surface. Histamine plays a central role in immediate hypersensitivity and allergic responses. The actions of histamine on bronchial smooth muscle and blood vessels account for many of the symptoms of the allergic response. Histamine is a leukocyte chemoattractant, plays a major role in regulating gastric acid secretion, and modulates neurotransmitter release. In addition, some drugs act directly on mast cells to release histamine, causing untoward effects.

Role in Allergic Responses

The principal target cells of immediate hypersensitivity reactions are mast cells and basophils (Schwartz, 1994). As part of the allergic response to an antigen, IgE antibodies are generated and bind to the surfaces of mast cells and basophils via specific high-affinity \( \text{F} \) receptors. This receptor, \( \text{Fc} \text{RI} \), consists of \( \alpha \), \( \beta \), and two \( \gamma \) chains (see Chapter 34). Antigen bridges the IgE molecules and via \( \text{Fc} \text{RI} \) activates signaling pathways in mast cells or
HISTAMINE, BRADYKININ, AND THEIR ANTAGONISTS

response (see discussion that follows). Stimulation of IgE receptors also activates PLA2, leading to the production of a host of mediators, including PAF and metabolites of arachidonic acid (Chapters 37 and 40). Kinins also are generated during some allergic reactions. Basic polypeptides often are effective histamine releasers, and within a limited range, their potency generally increases with the number of basic groups. For example, bradykinin is a poor histamine releaser, whereas kallidin (Lys-bradykinin) and substance P, with more positively charged amino acids, are more active (Johnson and Erdos, 1973). Some venoms, such as that of the wasp, contain potent histamine-releasing peptides. Basic polypeptides released on tissue injury constitute pathophysiological stimuli for secretion from mast cells and basophils.

**Release of Other Autacoids**

Stimulation of IgE receptors also activates PLA2, leading to the production of a host of mediators, including PAF and metabolites of arachidonic acid such as leukotrienes C4 and D4, which contract bronchial smooth muscle (Chapters 37 and 40). Kinins also are generated during some allergic responses. Thus, the mast cell secretes a variety of inflammatory mediators in addition to histamine, each contributing to aspects of the allergic response (see discussion that follows).

**Histamine Release by Drugs, Peptides, Venoms, and Other Agents**

Mechanical injury and many compounds, including a large number of therapeutic agents, stimulate the release of histamine from mast cells directly and without prior sensitization. Responses of this sort are most likely to occur following intravenous injections of certain categories of substances, particularly organic bases. Tubocurarine, succinylcholine, morphine, some antibiotics, radiocontrast media, and certain carbohydrate plasma expanders also may elicit the response. The phenomenon is one of clinical concern and may account for unexpected anaphylactoid reactions. Basic polypeptides often are effective histamine releasers, and over a limited range, their potency generally increases with the number of basic groups. For example, bradykinin is a poor histamine releaser, whereas kallidin (Lys-bradykinin) and substance P, with more positively charged amino acids, are more active (Johnson and Erdos, 1973). Some venoms, such as that of the wasp, contain potent histamine-releasing peptides. Basic polypeptides released on tissue injury constitute pathophysiological stimuli for secretion from mast cells and basophils.

**Increased Proliferation of Mast Cells and Basophils; Gastric Carcinoid Tumors**

In urticaria pigmentosa (cutaneous mastocytosis), mast cells aggregate in the upper corium and give rise to pigmented cutaneous lesions that sting when stroked. In systemic mastocytosis, overproliferation of mast cells is also found in other organs. Patients with these syndromes suffer a constellation of signs and symptoms attributable to excessive histamine release, including urticaria, dermographism, pruritus, headache, weakness, hypotension, flushing of the face, and a variety of GI effects, such as diarrhea or peptic ulceration. A variety of stimuli, including exertion, insect stings, exposure to heat, allergens (including drugs to which a patient is allergic), can activate mast cells and cause histamine release, as can organic bases (many drugs) that cause histamine release directly. In
myelogenous leukemia, elevation of blood basophils can result in histamine content high enough to cause flushing, pruritus, and hypotension. Management of these patients can be complicated by a large release of histamine after cytolysis, causing shock. Gastric carcinoid tumors secrete histamine, which is responsible for episodes of vasodilation as part of the patchy “geographical” flush.

**Gastric Acid Secretion**

Histamine acting at H2 receptors is a powerful gastric secretagogue, evoking copious secretion of acid from parietal cells (see Figure 49–1); it also increases the output of pepsin and intrinsic factor. The secretion of gastric acid from parietal cells also is caused by stimulation of the vagus nerve and by the enteric hormone gastrin. However, histamine is the dominant physiological mediator of acid secretion; blockade of H2 receptors not only antagonizes acid secretion in response to histamine but also inhibits responses to gastrin and vagal stimulation (see Chapter 49).

**CNS**

Histamine-containing neurons affect both homeostatic and higher brain functions, including regulation of the sleep-wake cycle, circadian and feeding rhythms, immunity, learning, memory, drinking, and body temperature. However, no human disease has yet been directly linked to dysfunction of the brain histamine system. Histamine, histidine decarboxylase, enzymes that metabolize histamine, and H1, H2, and H3 receptors are distributed widely but nonuniformly in the CNS. H1 receptors are associated with both neuronal and nonneuronal cells and are concentrated in regions that control neuroendocrine function, behavior, and nutritional state. Distribution of H2 receptors is more consistent with histaminergic projections than that of H1 receptors, suggesting that they mediate many of the postsynaptic actions of histamine. H2 receptors are concentrated in areas known to receive histaminergic projections, consistent with their function as presynaptic autoreceptors. Histamine inhibits appetite and increases wakefulness via H1 receptors.

*At least 20 alternately spliced H3 isoforms have been detected at the mRNA level. Eight of these isoforms, ranging in size from 329 to 445 residues, were found to be functionally competent by binding or signaling assays (see Esbenshade et al., 2008).
Physiological and Pharmacological Effects

Receptor-Effecter Coupling and Mechanisms of Action

Histamine receptors are GPCRs, coupling to second-messenger systems and producing effects (Simons, 2004) as noted in Table 39–1. H1 receptors couple to Gαi/11 and activate the PLC-IP3-Ca2+ pathway and its many possible sequelae, including activation of PKC, Ca2+-calmodulin–dependent enzymes (eNOS and various protein kinases), and PLA2. H1 receptors link to Gq to activate the adenyl cyclase–cyclic AMP–PKA pathway; H1 and H4 receptors couple to Gq/i to inhibit adenyl cyclase and decrease cellular cyclic AMP. Activation of H2 receptors also can activate MAP kinase and inhibit the Na+/H+ exchanger; activation of H2 receptors can mobilize stored Ca2+ (Simons and Simons, 2011). H1 and H4 receptors have about 1000-fold higher affinity for histamine (low nanomolar range) than do H2 and H3 receptors (low micromolar range). Activation of H1 receptors on vascular endothelium stimulates eNOS to produce NO, which diffuses to nearby smooth muscle cells to increase cyclic GMP and cause relaxation. Stimulation of H1 receptors in smooth muscle will mobilize Ca2+ and cause contraction, whereas activation of H3 receptors on the same smooth muscle cell will link via Gq to enhanced cyclic AMP accumulation, activation of PKA, and then to relaxation.

Pharmacological definition of H1, H2, and H3 receptors was possible through the use of relatively specific agonists and antagonists. Because the H4 receptor exhibits 35%–40% homology to isoforms of the H3 receptor, the two were initially harder to distinguish pharmacologically, but this has been resolved by the development of several H1- and H4-selective antagonists (Sander et al., 2008; Thurmond, 2015). 4-Methylhistamine and dimaprit, previously identified as specific H4 agonists, are actually more potent H3 agonists.

H1 and H2 Receptors

H1 and H2 receptors are distributed widely in the periphery and in the CNS and their activation by histamine can exert local or widespread effects (Simons and Simons, 2011). For example, histamine causes itching and stimulates secretion from nasal mucosa. It contracts many smooth muscles, such as those of the bronchi and gut, but markedly relaxes others, including those in small blood vessels. Histamine also is a potent stimulus of gastric acid secretion. Other, less-prominent effects include formation of edema and stimulation of sensory nerve endings. Bronchoconstriction and contraction of the gut are mediated by H1 receptors. In the CNS, H1 activation inhibits appetite and increases wakefulness. Gastric secretion results from the activation of H2 receptors. Some responses, such as vascular dilation, are mediated by both H1 and H2 receptor stimulation.

H3 and H4 Receptors

The H3 receptors are expressed mainly in the CNS, especially in the basal ganglia, hippocampus, and cortex (Haas et al., 2008). Presynaptic H3 receptors function as autoreceptors on histaminergic neurons, inhibiting histamine release and modulating the release of other neurotransmitters. H3 receptors are also found postsynaptically, especially in the basal ganglia, but their function is still being unravelled (Ellenbroek and Ghiabi, 2014). H3 agonists promote sleep, and H3 antagonists promote wakefulness.

The H4 receptors primarily are found in eosinophils, dendritic cells, mast cells, monocytes, basophils, and T cells but have also been detected in the GI tract, dermal fibroblasts, CNS, and primary sensory afferent neurons (Thurmond, 2015). Activation of H4 receptors has been associated with induction of cellular shape change, chemotaxis, secretion of cytokines, and upregulation of adhesion molecules, suggesting that H4 antagonists may be useful inhibitors of allergic and inflammatory responses (Thurmond, 2015).

Although specific H1 and H4 receptor antagonists have been developed, none of these agents has yet been FDA-approved for clinical use. Based on the functions of H3 receptors in the CNS, H3 antagonists have potential in the treatment of sleeping disorders, ADHD, epilepsy, cognitive impairment, schizophrenia, obesity, neuropathic pain, and Alzheimer disease. Because of the unique localization and function of H4 receptors, H4 antagonists are promising candidates to treat inflammatory conditions such as allergic rhinitis, asthma, rheumatoid arthritis, and possibly pruritus and neuropathic pain.

Feedback Regulation of Release

Stimulation of H3 receptor increases cyclic AMP and leads to feedback inhibition of histamine release from mast cells and basophils, whereas activation of H1 and H2 receptors has the opposite effect by decreasing cellular cyclic AMP. Activation of presynaptic H3 receptors inhibits histamine release from histaminergic neurons. Because H3 receptors have high constitutive activity, histamine release is tonically inhibited. H4 inverse agonists thus reduce receptor activation and increase histamine release from histaminergic neurons.

Cardiovascular System

Histamine dilates resistance vessels, increases capillary permeability, and lowers systemic blood pressure. In some vascular beds, histamine constricts veins, contributing to the extravasation of fluid and edema formation upstream in capillaries and postcapillary venules.

Vasodilation. Vasodilation is the most important vascular effect of histamine in humans and can result from activation of either the H1 or H2 receptor. H3 receptors have a higher affinity for histamine and cause Ca2+-dependent activation of eNOS in endothelial cells; NO diffuses to vascular smooth muscle, increasing cyclic GMP (see Table 39–1) and causing rapid and short-lived vasodilation. By contrast, activation of H4 receptors on vascular smooth muscle stimulates the cyclic AMP–PKA pathway, causing dilation that develops more slowly and is more sustained. As a result, H3 antagonists effectively counter small dilator responses to low concentrations of histamine but blunt only the initial phase of larger responses to higher concentrations of the amine.

Increased Capillary Permeability. Histamine’s effect on small vessels results in efflux of plasma protein and fluid into the extracellular spaces and an increase in lymph flow, causing edema. H1 receptor activation on endothelial cells is the major mediator of this response, leading to Gα2-mediated activation of RhoA and ROCK, which stimulates the contractile machinery of the cells and disrupts interendothelial junctions (Mikelis et al., 2015). The gaps between endothelial cells also may permit passage of circulating cells recruited to tissues during the mast cell response. Recruitment of circulating leukocytes is enhanced by H1 receptor–mediated expression of adhesion molecules (e.g., P-selectin) on endothelial cells.

Triple Response of Lewis. If histamine is injected intradermally, it elicits a characteristic phenomenon known as the triple response. This consists of the following:

- a localized “reddening” around the injection site, appearing within a few seconds, and maximal at about 1 min;
- a “flare” or red flush extending about 1 cm beyond the original red spot and developing more slowly; and
- a “wheat” or swelling that is discernible in 1–2 min at the injection site.

The initial red spot (a few millimeters) results from the direct vasodilator effect of histamine (H1 receptor–mediated NO production). The flare is due to histamine-induced stimulation of axon reflexes that cause vasodilation indirectly, and the wheal reflects histamine’s capacity to increase capillary permeability (edema formation).

Heart. Histamine affects both cardiac contractility and electrical events directly. It increases the force of contraction of both atrial and ventricular muscle by promoting the influx of Ca2+; and it speeds heart rate by hastening diastolic depolarization in the SA node. It also directly slows AV conduction to increase automaticity and, in high doses, can elicit arrhythmias. The slowed AV conduction involves mainly H1 receptors, while the other effects are largely attributable to H2 receptors and cyclic AMP accumulation. The direct cardiac effects of histamine given intravenously are overshadowed by baroreceptor reflexes stimulated by reduced blood pressure.

Extravascular Smooth Muscle

Histamine directly contracts or, more rarely, relaxes various extravascular smooth muscles. Contraction is due to activation of H1 receptors on smooth muscle to increase intracellular Ca2+, and relaxation is mainly due...
to activation of H<sub>1</sub> receptors. Although the spasmogenic influence of H<sub>1</sub> receptors is dominant in human bronchial muscle, H<sub>2</sub> receptors with dilator function also are present. Thus, histamine-induced bronchospasm in vitro is potentiated slightly by H<sub>2</sub> blockade. Patients with bronchial asthma and certain other pulmonary diseases are much more sensitive to the bronchoconstrictor effects of histamine.

**Peripheral Nerve Endings**

Histamine stimulates various nerve endings, causing sensory effects. In the epidermis, it causes itch; in the dermis, it evokes pain, sometimes accompanied by itching. Stimulant actions on nerve endings, including autonomic afferents and efferents, contribute to the “flare” component of the triple response and to indirect effects of histamine on the bronchi and other organs.

**Histamine Shock**

Histamine given in large doses or released during systemic anaphylaxis causes a profound and progressive fall in blood pressure. As the small blood vessels dilate, they trap large amounts of blood, their permeability increases, and plasma escapes from the circulation. These effects, resembling surgical or traumatic shock, diminish effective blood volume, reduce venous return, and greatly lower cardiac output.

**Histamine Toxicity From Ingestion**

Histamine is the toxin in food poisoning from spoiled scombroid fish such as tuna. Symptoms include severe nausea, vomiting, headache, flushing, and sweating. Histamine toxicity also can follow red wine consumption in persons with a diminished ability to degrade histamine. The symptoms of histamine poisoning can be suppressed by H<sub>1</sub> antagonists.

**Histamine Receptor Antagonists**

**H<sub>1</sub> Receptor Antagonists**

**HISTORY**

Antihistamine activity was first demonstrated by Bovet and Staub in 1937 with one of a series of amines with a phenolic ether moiety. The substance, 2-isopropyl-5-methylphenoxy-ethylidethyl-amine, protected guinea pigs against several lethal doses of histamine but was too toxic for clinical use. By 1944, Bovet and his colleagues had described pyrilmamine maleate, an effective histamine antagonist of this category. The discovery of highly effective diphenhydramine and triprolidine soon followed. In the 1980s, non-sedating H<sub>1</sub> histamine receptor antagonists were developed for treatment of allergic diseases. Despite success in blocking allergic responses to histamine, the H<sub>1</sub> antihistamines failed to inhibit a number of other responses, notably gastric acid secretion. The discovery of H<sub>2</sub> receptors and H<sub>1</sub> antagonists by Black and colleagues provided a new class of agents that antagonized histamine-induced acid secretion (Black et al., 1972); the pharmacology of these drugs (e.g., cimetidine, famotidine) is described in Chapter 49.

**Pharmacological Properties**

All the available H<sub>1</sub> receptor “antagonists” are actually inverse agonists (see Chapter 3) that reduce constitutive activity of the receptor and compete with histamine binding to the receptor (Simons, 2004). The pharmacological actions and therapeutic applications of these antagonists can be largely predicted from knowledge of the location and mode of signaling of the histamine receptors.

**Chemistry.** Like histamine, many H<sub>1</sub> antagonists contain a substituted ethylamine moiety (the black portion on the figure that follows). Unlike histamine, which has a primary amino group and a single aromatic ring, most H<sub>1</sub> antagonists have a tertiary amino group linked by a two- or three-atom chain to two aromatic substituents (in red) and conform to the general formula:

\[
\text{Ar}_1\overset{X}{\overset{C}{\overset{C}{\overset{N}{\text{Ar}_2}}}}
\]

where Ar is aryl and X is a nitrogen or carbon atom or a —C—O— ether linkage to the β-aminoethyl side chain. Sometimes, the two aromatic rings are bridged, as in the tricyclic derivatives, or the ethylamine may be part of a ring structure. Figure 39–3 shows the varied structures of representative H<sub>1</sub> antagonists built around this framework and constitute the several generations of compounds.

**Effects on Physiological Systems**

**Smooth Muscle.** The H<sub>1</sub> antagonists inhibit most of the effects of histamine on smooth muscles, especially the constriction of respiratory smooth muscle. H<sub>1</sub> antagonists inhibit the more rapid vasodilator effects mediated by activation of H<sub>2</sub> receptors on endothelial cells (synthesis/release of NO and other mediators) at lower doses of histamine. They also inhibit venous constriction seen in some vascular beds.

**Capillary Permeability.** H<sub>1</sub> antagonists strongly block the increased capillary permeability and formation of edema and wheal caused by histamine.

**Flare and Itch.** H<sub>1</sub> antagonists suppress the action of histamine on nerve endings, including the flare component of the triple response and the itching caused by intradermal injection.

**Exocrine Glands.** H<sub>1</sub> antagonists do not suppress gastric secretion. However, the antimuscarinic properties of many H<sub>1</sub> antagonists may contribute to lessened secretion in cholinergically innervated glands and reduce ongoing secretion in, for example, the respiratory tree.

**Immediate Hypersensitivity Reactions: Anaphylaxis and Allergy.** During hypersensitivity reactions, histamine is one of the many potent autacoids released, and its relative contribution to the ensuing symptoms varies widely with species and tissue. The protection afforded by H<sub>1</sub> antagonists varies accordingly. In humans, edema formation and itch are effectively suppressed. Other effects, such as hypotension, are less well antagonized. H<sub>1</sub> antagonists are ineffective in blocking bronchoconstriction due to asthma.

**Histamine Receptor Antagonists**

**Mast Cell–Stabilizing and Anti-inflammatory Properties.** Many second-generation H<sub>1</sub> antagonists (e.g., cetirizine, desloratadine, fexofenadine, olopatadine, ketotifen, and others) exhibit mast cell–stabilizing effects, resulting in reduced release of mast cell mediators during an allergic response (Levi-Schaffer and Eliahar, 2009). These agents also have anti-inflammatory properties, which can include reduced cytokine secretion, decreased adhesion molecule expression, and inhibition of eosinophil infiltration. These effects can be both H<sub>1</sub> receptor dependent and independent, but precise mechanisms are still unclear, and it is unknown what role they play at normal therapeutic doses of these drugs. There is some evidence that H<sub>1</sub> antagonists with these additional properties may be more effective in the topical treatment of allergic conjunctivitis (Abelson et al., 2015).

**CNS.** The first-generation H<sub>1</sub> antagonists can both stimulate and depress the CNS (Simons and Simons, 2011). Stimulation occasionally is encountered in patients given conventional doses; the patients become restless, nervous, and unable to sleep. Central excitation also is a striking feature of overdose, which commonly results in convulsions, particularly in infants. Central depression, on the other hand, usually accompanies therapeutic doses of the older H<sub>1</sub> antagonists. Diminished alertness, slowed reaction times, and somnolence are common manifestations. Patients vary in their susceptibility and responses to individual drugs. The ethanolamines (e.g., diphenhydramine) are particularly prone to causing sedation. Because of
CHAPTER 39

HISTAMINE, BRADYKININ, AND THEIR ANTAGONISTS

Simons, 2011). In test systems, the atypical antipsychotic agent clozapine is an effective H1 antagonist, a weak H3 antagonist, and an H4 receptor agonist. The H1 antagonist activity of typical and atypical antipsychotic drugs is responsible for the propensity of these agents to cause weight gain.

Anticholinergic Effects. Many of the first-generation H1 antagonists tend to inhibit muscarinic cholinergic responses and may be manifest during clinical use (Simons and Simons, 2011). Some H1 antagonists also can be used to treat motion sickness (see Chapters 9 and 50), probably as a result of their anticholinergic properties. Indeed, promethazine has perhaps the strongest muscarinic-blocking activity among these agents and is the most effective H1 antagonist in combating motion sickness. The second-generation H1 antagonists have no effect on muscarinic receptors (Simons and Simons, 2011).

Local Anesthetic Effect. Some H1 antagonists have local anesthetic activity, and a few are more potent than procaine. Promethazine is especially active. However, the concentrations required for this effect are much higher than those that antagonize histamine’s interactions with its receptors.

ADME. The H1 antagonists are well absorbed from the GI tract. Following oral administration, peak plasma concentrations are achieved in 1–3 h, and effects usually last 4–6 h for first-generation agents; however, some of the drugs are much longer acting, as are most second-generation H1 antagonists (del Cuvillo et al., 2006; Simons, 2004) (Table 39–2). These agents are distributed widely throughout the body, including the CNS for the first-generation agents. Peak concentrations of these drugs in the skin may persist long after plasma levels have declined. Thus, inhibition of “wheal-and-flare” responses to the intradermal injection of histamine or allergen can persist for 36 h or more after initial treatment and up to 7 days after discontinuation of treatment in patients who regularly use an H1 antagonist for 1 week or more (del Cuvillo et al., 2006).

All first-generation and most second-generation H1 antagonists are metabolized by CYPs and little, if any, is excreted unchanged in the urine; most appears there as metabolites (Bartra et al., 2006; Simons, 2004). Exceptions are cetirizine and acrivastine (<40% metabolized) and fexofenadine, levocetirizine, and epinastine (<10% metabolized). Cetirizine, levocetirizine, and acrivastine are excreted primarily into the urine; fexofenadine is mainly excreted in the feces, and epinastine is excreted in both urine (55%) and feces (30%).

The H1 antagonists that are metabolized are eliminated more rapidly by children than by adults and more slowly in those with severe liver disease. These antagonists also have higher potential for drug interactions. For example, plasma levels of H1 antagonists may be reduced when coadministered with drugs that induce CYP synthesis (e.g., benzodiazepines) or elevated when taken with drugs that compete with or inhibit the same CYP isoform (e.g., erythromycin, ketoconazole, antidepressants) (Bartra et al., 2006; Simons, 2004). Clinically relevant interactions are more likely with first-generation than second-generation drugs, which have a higher therapeutic index. However, two second-generation H1 antagonists marketed previously, terfenadine and astemizole, were found in rare cases to prolong the QTc interval and induce a potentially fatal arrhythmia, torsade de pointes, due to their capacity to inhibit a cardiac K+ channel, Ikr, when their metabolism was impaired and their plasma concentrations rose too high, due, for instance, to liver disease or to drugs that inhibited the CYP3A family (Bartra et al., 2006; Simons, 2004) (see Chapter 30). This led to the withdrawal of terfenadine and astemizole from the market. Astemizole and an active hydroxylated metabolite naturally have very long half-lives. Terfenadine is a prodrug,

*For a discussion of phenothiazines, see Chapter 16.

1Duration of action of H₁ antihistamines by objective assessment of suppression of histamine- or allergen-induced symptoms is longer than expected from measurement of plasma concentrations or terminal elimination t₁/₂ values.

2Preparations are designated as follows: O, oral solids; L, oral liquids; I, injection; S, suppository; SR, sustained release; T, topical. Many H₁ receptor antagonists also are available in preparations that contain multiple drugs. SR forms dissuade pseudoephedrine extraction for methamphetamine production.

3Dimenhydrinate is a combination of diphenhydramine and 8-chlorotheophylline in equal molecular proportions.

4Also has antiserotonin properties.

5Has mild sedating effects.
metabolized by hepatic CYP3A4 to fexofenadine, which is its replacement and lacks noticeable cardiotoxicity. In vitro testing for a new drug’s capacity to inhibit \( I_{50} \) is now available.

**Therapeutic Uses**

The \( H_1 \) antagonists are used for treatment of various immediate hypersensitivity reactions. The central properties of some of the drugs also are of therapeutic value for suppressing motion sickness or for sedation.

**Allergic Diseases.** \( H_1 \) antagonists are useful in acute types of allergy that present with symptoms of rhinitis, urticaria, and conjunctivitis (Simons and Simons, 2011). Their effect is confined to the suppression of symptoms attributable to the histamine released by the antigen-antibody reaction. In bronchial asthma, histamine antagonists have limited efficacy and are not used as sole therapy (see Chapters 38 and 40). In the treatment of systemic anaphylaxis, where autacoids other than histamine are important, the mainstay of therapy is epinephrine; histamine antagonists have only a subordinate and adjuvant role. The same is true for severe angioedema, in which laryngeal swelling constitutes a threat to life (see Chapter 12).

Certain allergic dermatoses respond favorably to \( H_1 \) antagonists. The benefit is most striking in acute urticaria. \( H_1 \) antagonists are also first-line therapy for chronic urticaria but may require doses up to four times higher than that approved for treating rhinitis; patients refractory to high-dose \( H_1 \) antagonists should be switched to drugs targeting the immune response (Viegas et al., 2014). \( H_1 \) antagonists have a place in the treatment of pruritus. Some relief may be obtained in many patients with atopic and contact dermatitis (although topical corticosteroids are more effective) and in such diverse conditions as insect bites and poison ivy. The urticarial and edematous lesions of serum sickness respond to H1 antagonists, but fever and arthralgia often do not.

**Common Cold.** \( H_1 \) antagonists are without value in combating the common cold. The weak anticholinergic effects of the older agents may tend to lessen rhinorrhea, but this drying effect may do more harm than good, as may their tendency to induce somnolence.

**Motion Sickness, Vertigo, and Sedation.** Scopolamine, the muscarinic antagonist, given orally, parenterally, or transdermally, is the most effective drug for the prophylaxis and treatment of motion sickness. Some \( H_1 \) antagonists are useful for milder cases and have fewer adverse effects. These drugs include dimenhydrinate and the piperazines (e.g., cyclizine, meclizine). Promethazine, a phenothiazine, is more potent and more effective, and its additional antiemetic properties may be of value in reducing vomiting; however, its pronounced sedative action usually is disadvantageous. Whenever possible, the various drugs should be administered about 1 h before the anticipated motion. Treatment after the onset of nausea and vomiting rarely is beneficial. Some \( H_1 \) antagonists, notably dimenhydrinate and meclizine, often are of benefit in vestibular disturbances such as Ménière disease and in other types of true vertigo. Only promethazine is useful in treating the nausea and vomiting subsequent to chemotherapy or radiation therapy for malignancies; however, other, more effective, antiemetic drugs (e.g., 5HT3 antagonists) are available (see Chapter 50). Diphenhydramine can reverse the extrapyramidal side effects caused by antipsychotics (see Chapter 16). The tendency of some \( H_1 \) receptor antagonists to produce somnolence has led to their use as hypnotics. \( H_1 \) antagonists, principally diphenhydramine, often are present in various proprietary over-the-counter remedies for insomnia. The sedative and mild antianxiety activities of hydroxyzine contribute to its use as an anxiolytic.

**Adverse Effects**

The most frequent side effect of first-generation \( H_1 \) antagonists is sedation. Concurrent ingestion of alcohol or other CNS depressants produces an additive effect that impairs motor skills. Other untoward central actions include dizziness, tinnitus, lassitude, incoordination, fatigue, blurred vision, diplopia, euphoria, nervousness, insomnia, and tremors. Other potential side effects, including loss of appetite, nausea, vomiting, epigastric distress, and constipation or diarrhea, may be reduced by taking the drug with meals. \( H_1 \) antagonists such as cyproheptadine may increase appetite and cause weight gain. Other side effects, owing to the antimuscarinic actions of some first-generation \( H_1 \) antagonists, include dryness of the mouth and respiratory passages (sometimes inducing cough), urinary retention or frequency, and dysuria. These effects are not observed with second-generation \( H_1 \) antagonists. Allergic dermatitis is not uncommon; other hypersensitivity reactions include drug fever and photosensitization. Hematological complications, such as leukopenia, agranulocytosis, and hemolytic anemia, are very rare.

Because \( H_1 \) antihistamines cross the placenta, caution is advised for women who are or may become pregnant (Simons and Simons, 2011). Several antihistamines (e.g., azelastine, hydroxyzine, fexofenadine) had teratogenic effects in animal studies, whereas others (e.g., chlorpheniramine, diphenhydramine, cetirizine, loratadine) did not. A recent systematic review concluded that antihistamines are unlikely to be strong risk factors for major birth defects (Gilboa et al., 2014). A combination drug consisting of the \( H_1 \) antagonist doxylamine and vitamin B6 (pyridoxine) was approved in 1956 for treating the nausea and vomiting of pregnancy and then voluntarily removed in 1983 due to concerns over birth defects. Subsequent analyses showed the drug caused no increased risk of birth defects, and in 2013 it was reapproved for the same indication in a fixed-dose, delayed-release formulation. Antihistamines can be excrated in small amounts in breast milk, and first-generation antihistamines taken by lactating mothers may cause symptoms such as irritability, drowsiness, or respiratory depression in the nursing infant.

In acute poisoning with first-generation \( H_1 \) antagonists, their central excitatory effects constitute the greatest danger. The syndrome includes hallucinations, excitement, ataxia, incoordination, atetosis, and convulsions, fixed, dilated pupils with a flushed face, together with sinus tachycardia, urinary retention, dry mouth, and fever. The syndrome exhibits a remarkable similarity to that of atropine poisoning. Terminally, there is deepening coma with cardiorespiratory collapse and death usually within 2–18 h. Treatment is along general symptomatic and supportive lines. Overdoses of second-generation \( H_1 \) antagonists have not been associated with significant toxicity (Simons and Simons, 2011).

**Pediatric and Geriatric Indications and Problems.** Although little clinical testing has been done, second-generation antihistamines are preferred for elderly patients (>65 years of age), especially those with impaired cognitive function, because of the sedative and anticholinergic effects of first-generation drugs (Simons, 2004). In addition, a recent prospective study in participants 65 years old and older without dementia showed a significant 10-year cumulative dose-response relationship between use of anticholinergics (first-generation \( H_1 \) antagonists among the most common) and risk of dementia, primarily Alzheimer disease (Gray et al., 2015).

First-generation antihistamines are not recommended for use in children because their sedative effects can impair learning and school performance. The second-generation drugs have been approved by the FDA for use in children and are available in appropriate lower-dose formulations (e.g., chewable or rapidly dissolving tablets, syrup). Use of over-the-counter cough and cold medicines (containing mixtures of antihistamines, decongestants, antitussives, expectorants) in young children has been associated with serious side effects and deaths. In 2008, the FDA recommended that they should not be used in children less than 2 years of age, and drug manufacturers affiliated with the Consumer Healthcare Products Association voluntarily relabeled products “do not use” for children less than 4 years of age.

**Available \( H_1 \) Antagonists**

Summarized next are notable properties of a number of \( H_1 \) antagonists, grouped by their chemical structures. Representative preparations are listed in Table 39–2.

**First-Generation Dibenzoxepin Tricyclic (Doxepin).** Doxepin is marketed as a tricyclic antidepressant (see Chapter 15). It also is one of the most potent \( H_1 \) antagonists and has significant \( H_1 \) antagonist activity, but this does not translate into greater clinical effectiveness. It can cause
drowsiness and is associated with anticholinergic effects. Doxepin is better tolerated by patients with depression than those who are not depressed, for whom even small doses may cause disorientation and confusion. **Second-Generation Dibenzoepine Tricyclic (Olopatadine).** Olopatadine is a topical H₃ antagonist with additional mast cell–stabilizing and anti-inflammatory properties. In drop form, it is an effective treatment of allergic conjunctivitis and as a spray helps reduce the nasal symptoms of allergic rhinitis.

**Ethanolamines (Prototype: Diphenhydramine).** The ethanolamines possess significant antimuscarinic activity and have a pronounced tendency to induce sedation. About half of those treated acutely with conventional doses experience somnolence. The incidence of GI side effects, however, is low with this group.

**First-Generation Alkylamines (Prototype: Chlorpheniramine).** The first-generation alkylamines are among the most potent H₁ antagonists. They are widely used for skin allergies; its considerable CNS-depressant activity may contribute to its prominent antipruritic action, and it is also used as a sedative and antianxiety agent. Cyclizine and meclizine have been used as a sedative and antianxiety agent. Cyclizine and meclizine have been used as a sedative and antianxiety agent.

**First-Generation Piperidine (Cyproheptadine).** Cyproheptadine is a derivative of the first-generation alkylamine triprolidine and may exhibit a somewhat higher incidence of mild sedation than other second-generation H₁ antagonists.

**Second-Generation Piperazine (Prototype: Terfenadine).** Second-generation piperazine antihistamines tend to have lower antimuscarinic effects, resulting in a lower incidence of the CNS-dépressive side effects. These agents are less likely to cause drowsiness and are more suitable for daytime use, but a significant proportion of patients still experience sedation. Side effects involving CNS stimulation are more common than with other groups.

**Second-Generation Alkylamines (Prototype: Acrivastine).** Acrivastine is a derivative of the first-generation alkylamine triprolidine and may exhibit a somewhat higher incidence of mild sedation than other second-generation H₁ antagonists.

**Second-Generation Piperazines (Cetirizine).** Cetirizine has minimal anticholinergic effects. It also has negligible penetration into the brain but is associated with a somewhat higher incidence of drowsiness than most other second-generation H₁ antagonists. The active enantiomer levocetirizine has slightly greater potency and may be used at half the dose with less resultant sedation. Cetirizine and levocetirizine have additional mast cell–stabilizing and anti-inflammatory properties.

**Phenothiazines (Prototype: Promethazine).** Promethazine, which has prominent sedative and considerable anticholinergic effects, and its many congeners are used primarily for their antiemetic effects (see Chapter 50).

**First-Generation Piperidine (Cyproheptadine).** Cyproheptadine is a second-generation piperidine antihistamine. It has a greater anticholinergic profile than the first-generation piperidines and is more suitable for daytime use. However, it can cause drowsiness, and may exhibit a somewhat higher incidence of mild sedation than other second-generation H₁ antagonists.

**Second-Generation Piperidines (Prototype: Loratadine).** Terfenadine and astemizole, early second-generation drugs, are no longer marketed because of their potential for causing a rare, but potentially fatal, arrhythmia, torsade de points (see previous discussion). Terfenadine was replaced by fexofenadine, an active metabolite that lacks the toxic side effects of terfenadine, is not sedating, and retains the antiallergic properties of the parent compound. Another antihistamine of this class developed using this strategy is desloratadine, an active metabolite of loratadine. These agents lack significant anticholinergic actions and penetrate poorly into the CNS. Taken together, these properties appear to account for the low incidence of side effects of piperidine antihistamines. All members of this class have mast cell–stabilizing and anti-inflammatory properties. Although the therapeutic significance of these additional effects is unclear for the drugs administered orally, they appear to provide additional benefit when used in topical formulations to treat allergic conjunctivitis. Alclafadine has additional antagonist activity on H₄ receptors, which likely explains its superiority to other topical H₄ antagonists in reducing the ocular itch of allergic conjunctivitis (Thurmond, 2015).

### H₃ Receptor Antagonists

The H₃ receptors are presynaptic autoreceptors on histaminergic neurons that originate in the tuberomammillary nucleus in the hypothalamus and project throughout the CNS, most prominently to the hippocampus, amygdala, nucleus accumbens, globus pallidus, striatum, hypothalamus, and cortex (Haas et al., 2008; Sander et al., 2008). The activated H₃ receptor depresses neuronal firing at the level of cell bodies/dendrites and decreases histamine release from depolarized terminals. Thus, H₃ agonists decrease histaminergic transmission, and antagonists increase it.

The H₃ receptors also are presynaptic heteroreceptors on a variety of neurons in brain and peripheral tissues, and their activation inhibits transmitter release from noradrenergic, serotonergic, GABAergic, cholinergic, and glutamatergic neurons, as well as pain-sensitive C fibers. H₃ receptors in the brain have significant constitutive activity in the absence of agonist; consequently, inverse agonists reduce this constitutive activity, withdraw inhibition of transmitter release, and thereby promote transmitter release (activation of these neurons).

The H₃ antagonists/ inverse agonists have a wide range of central effects; for example, they promote wakefulness, improve cognitive function (e.g., enhance memory, learning, and attention), and reduce food intake. As a result, there is considerable interest in developing H₃ antagonists for possible treatment of sleeping disorders, ADHD, epilepsy, cognitive impairment, schizophrenia, obesity, neuropathic pain, and Alzheimer disease (Haas et al., 2008; Sander et al., 2008). Thioperamide was the first “specific” H₃ receptor/ inverse agonist available experimentally, but it was equally effective at the H₁ receptor. A number of other imidazole derivatives have been developed as H₃ antagonists, including clobenpropit, ciproxifan, and proxafyn, but the imidazole ring enhances binding to the H₁ receptor and CYPs. Because of this, more selective nonimidazole H₃ antagonists/inverse agonists (e.g., tiprolisant) were developed (Haas et al., 2008; Sander et al., 2008), and some are now in phase 2 and 3 clinical trials.

### H₄ Receptor Antagonists

The H₄ receptors are expressed on cells with inflammatory or immune functions and can mediate histamine-induced chemotaxis, induction of cell shape change, secretion of cytokines, and upregulation of adhesion molecules (Thurmond et al., 2008). The H₄ receptors also have a role in pruritus and neuropathic pain. Because of the unique localization and function of H₄ receptors, H₄ antagonists are promising candidates to treat inflammatory conditions and possibly pruritus and neuropathic pain (Thurmond, 2015). The H₄-specific antagonist JNJ-39758979 has been tested in phase 1 and 2 clinical trials for treatment of persistent asthma, pruritus, dermatitis, and rheumatoid arthritis.

The H₄ receptor has the highest homology with the H₁ receptor and binds many H₁ ligands, especially those with imidazole rings, although sometimes with different effects (Thurmond et al., 2008). For example, thioperamide is an effective inverse agonist at both H₁ and H₄ receptors, whereas H₄ inverse agonist clobenpropit is a partial agonist of the H₄.
activate factor XII to start the positive-feedback loop, and cleave HMW (Hsp90) or prolylcarboxypeptidase to generate kallikrein, which can then prekallikrein–HMW kininogen complex by either heat shock protein 90 binding of the HMW kininogen–prekallikrein heterodimer to a mul-
on the system. In vivo, the order of this process can be reversed. The rapidly further activates factor XII, thereby exerting a positive feedback activation and, in turn, activates prekallikrein. Importantly, kallikrein

**Bradykinin, Kallidin, and Their Antagonists**

In the 1920s and 1930s, Frey, Kraut, and Werle characterized a hypotensive substance in urine, which was also found in other fluids and tissues, and named this material kallikrein after a Greek synonym for the pancreas, an especially rich source (Werle, 1970). It was established that kallikrein generates a pharmacologically active substance from an inactive precursor present in plasma; the active substance, kallidin, proved to be a polypeptide cleaved from a plasma globulin (Werle, 1970). Rocha e Silva, Beraldo, and associates later reported that trypsin and certain snake venoms acted on plasma globulin to produce a substance that lowered blood pressure and caused a slowly developing contraction of the gut (Rocha e Silva et al., 1949); they named it bradykinin, derived from the Greek words brady, meaning “slow,” and kinein, meaning “to move.” In 1960, bradyk

**The Endogenous Kallikrein–Kininogen–Kinin System**

The nonapeptide bradykinin and decapeptide kallidin (Iloyl-bradykinin) (Figure 39–4) are cleaved from α2 globulins termed kininogens (Figure 39–4). There are two kininogens: HMW kininogen and LMW kininogen. A number of serine proteases will generate kinins, but the two highly specific proteases that release bradykinin and kallidin from the kininogens are termed kallikreins.

**Kallikreins**

Bradykinin and kallidin are cleaved from HMW or LMW kininogens by plasma or tissue kallikrein, respectively (see Figure 39–4). Plasma kallikrein and tissue kallikrein are distinct enzymes that are activated by different mechanisms (Bhoola et al., 1992). Plasma prekallikrein is an inactive protein of about 88 kDa that complexes with its substrate, HMW kininogen. The ensuing proteolytic cascade is normally restrained by the protease inhibitors present in plasma, most importantly the activated first component of complement (C1-INH) and α2 macroglobulin. Under experimental conditions, the kallikrein–kinin system is activated by the binding of factor XII (Hageman factor) to negatively charged surfaces. Bound factor XII, a protease that is common to both the kinin and the kallikreins

**Kininos**

The two substrates for the kallikreins, HMW kininogen (120 kDa) and LMW kininogen (66 kDa), are derived from a single gene by alternative splicing. The first 401 amino acids are identical (through the bradykinin sequence and 12 additional residues) and then the sequences diverge, with kallikrein to generate bradykinin (Kaplan and Joseph, 2014). This process may contribute to the symptoms of hereditary angioedema in patients that lack C1-INH.

Human tissue kallikrein is 1 of 15 gene family members with high sequence identity that are clustered at chromosome 19q13.4 (Prassas et al., 2015). However, the classical “tissue kallikrein,” hK1, is the only family member to readily generate kallidin from LMW kininogen. Tissue 

**Metabolism of Kinins**

The decapeptide kallidin is about as active as the nonapeptide bradykinin, even without conversion to bradykinin, which occurs when the N-terminal lysine residue is removed by an aminopeptidase (see Figure 39–4). The t1/2 of kinins in plasma is only about 15 sec; 80%–90% of the kinins may

**SOURCE**

Hyp, trans-4-hydroxy-Pro; Thi, β-(2-thienyl)-Ala; Tic, [d]-1,2,3,4-tetrahydropyridin-3-yl-carbonyl; Oic, (3a,7a)-octahydroindol-2-yl-carbonyl.
and kallidin; thus, its effects are prohypertensive, and ACE inhibitors are effective antihypertensive agents. The B2 receptor mediates most of bradykinin’s effects under normal circumstances, whereas synthesis of the B1 receptor is induced by inflammatory mediators in inflammatory conditions. Both B1 and B2 receptors stimulate production of NO via Gi and an acute MAP kinase–dependent activation of eNOS. On smooth muscle cells, activation of NO, which causes cyclic GMP accumulation and relaxation in neighboring smooth muscle cells. However, in endothelial cells under inflammatory conditions, COX products are not produced, and the principal catabolizing enzyme in the lung and other vascular beds is kininase II, or ACE, a membrane-anchored peptidase on the surface of endothelial cells (see Chapter 26). Removal of the C-terminal arginine residue, producing [des-Arg9]-bradykinin, causes contraction. B1 and B2 receptors also can couple through Gq to activate PLA2, causing the release of arachidonic acid and the local generation of prostanoids (PGs) and other metabolites such as EDHF. Kallikrein also plays a role in the intrinsic blood coagulation pathway (see Chapter 32).

Carboxypeptidase N is expressed in the liver and constitutively secreted into the blood. A rare familial carboxypeptidase N deficiency was associated with angioedema or urticaria, possibly due to increased bradykinin (Skidgel and Erdös, 2007). Carboxypeptidase M, which cleaves the C-terminal Arg of bradykinin about 3-fold faster than carboxypeptidase N, is a widely distributed plasma membrane–bound enzyme that is also found on lung microvascular endothelial cells (Zhang et al., 2013a). Finally, aminopeptidase P is a membrane enzyme on epithelial and endothelial cells that can cleave the N-terminal arginine of bradykinin, rendering it inactive and susceptible to further cleavage by dipeptidyl peptidase IV (Erdös and Skidgel, 1997) (Figure 39–5).

Kinin Receptors and Their Signaling Pathways

The B1 and B2 kinin receptors are GPCRs whose signaling mediates most of the biological effects of the kallikrein-kinin system (Leeb-Lundberg et al., 2005). The B1 receptor is expressed in most normal tissues, where it selectively binds intact bradykinin and kallidin (see Table 39–3 and Figures 39–4 and 39–5). The B2 receptor mediates the effects of bradykinin and kallidin under normal circumstances, whereas synthesis of the B2 receptor is induced by inflammatory conditions. The B2 receptor is activated by the
C-terminal des-Arg metabolites of bradykinin and kallidin produced by the actions of carboxypeptidases N and M. Interestingly, carboxypeptidase M and the B1 receptor interact on the cell surface to form an efficient signaling complex that enhances B1 receptor agonist affinity and can lead to allosteric activation of B1 receptor signaling by substrate binding to carboxypeptidase M (Zhang et al., 2013a, 2013b). B1 receptors are normally absent or expressed at low levels in most tissues. B1 receptor expression is upregulated by tissue injury and inflammation and by cytokines, endotoxins, and growth factors. Carboxypeptidase M expression also is increased by cytokines, to such a degree that B1 receptor effects may predominate over B2 effects (Zhang et al., 2013a).

Both B1 and B2 receptors couple through Gq to activate PLC and increase intracellular Ca2+; the physiological response depends on receptor distribution on particular cell types, the cell environment, and mediators generated (Leeb-Lundberg et al., 2005). For example, on normal endothelial cells, activation of B1 receptors results in Gq and Ca2+-calmodulin–dependent activation of eNOS and short-term generation of NO, which causes cyclic GMP accumulation and relaxation in neighboring smooth muscle cells. However, direct activation of B1 or B2 receptors on smooth muscle cells leads to coupling through Gq and increased [Ca2+]i, resulting in contraction.

Inflammatory conditions alter receptor signaling in endothelial cells, such that B1 receptor stimulation leads to prolonged eNOS-derived NO that depends on Gq-mediated activation of MEK1/2 and JNK1/2, whereas B2 receptor activation cooperates through Gq and MAP kinase activation to cause ERK1/2-mediated phosphorylation and activation of iNOS, which generates prolonged, high-output NO (Kuhr et al., 2010; Lowry et al., 2013). Both B1 and B2 receptor stimulation activate the pro-inflammatory transcription factor NF-kB coupled through Gq, and βγ subunits and also activate the MAP kinase pathway (Leeb-Lundberg et al., 2005). B1 and B2 receptors also can couple through Gq to activate PLA2, causing the release of arachidonic acid and the local generation of metabolites such as prostaglandins and vasodilator EETs (Campbell and Falck, 2007).

The B1 and B2 receptors differ in their time courses of downregulation after agonist stimulation: the B2 receptor response is rapidly desensitized, whereas the B1 response is not (Leeb-Lundberg et al., 2003). This likely is due to modification at a Ser/Thr-rich cluster present in the C-terminal tail of the B2 receptor that is not conserved in the B1 receptor sequence. However, the B2 receptor can heterodimerize with the B1 receptor and in this form can be cross desensitized by activation of the B1 receptor with agonist (Zhang et al., 2015).

#### Functions and Pharmacology of Kallikreins and Kinins

The utility of specific kinin receptor antagonists currently is being investigated in diverse areas such as pain, inflammation, chronic inflammatory diseases, and the cardiovascular system (Campos et al., 2006). The beneficial effects of ACE inhibitor therapy rest in part on enhancing bradykinin activity (e.g., on the heart, kidney, blood pressure; see Chapter 26); this has led to the suggestion that kinin agonists could be therapeutically beneficial (Hetsch, 2003).

**Pain.** The kinins are powerful algesic agents that cause an intense burning pain when applied to the exposed base of a blister. Bradykinin excites primary sensory neurons and provokes the release of neuropeptides such as substance P, neurokinin A, and calcitonin gene–related peptide. Although there is overlap, B1 receptors generally mediate acute bradykinin algesia, whereas the pain of chronic inflammation appears to involve increased numbers and activation of B2 receptors.

**Inflammation.** Kinins participate in a variety of inflammatory conditions (Bhoola et al., 1992; Leeb-Lundberg et al., 2005). Plasma kinins increase permeability in the microcirculation, acting on the small venules to cause disruption of the interendothelial junctions. This, together with an increased hydrostatic pressure gradient, causes edema. Edema, coupled with stimulation of nerve endings, results in a wheal-and-flare response to intradermal injection. In acute attacks of hereditary angioedema, excess bradykinin is formed, as reflected by depletion of the upstream components of the kinin cascade, and is a primary mediator of swelling, laryngeal edema, and abdominal pain (Walford and Zuraw, 2014).

The B2 receptors on inflammatory cells (e.g., macrophages) can elicit production of the inflammatory mediators IL-1 and TNF-α. Kinin levels are increased in a number of chronic inflammatory diseases and may be significant in gout, disseminated intravascular coagulation, inflammatory bowel disease, rheumatoid arthritis, or asthma. In addition, kinins and their receptors are associated with a variety of neuroinflammatory disorders, including neuropathic pain in diabetes, autoimmune encephalomyelitis, and Alzheimer disease. Kinins may contribute to the skeletal changes seen in chronic inflammatory states; kinins stimulate bone resorption through B1 and possibly B2 receptors, perhaps by osteoblast-mediated osteoclast activation (see Chapter 44).

**Respiratory Disease.** The kinins have been implicated in allergic airway disorders such as asthma and rhinitis (Abraham et al., 2006). Inhalation of kinins causes bronchospasm mimicking an asthma attack in asthmatic patients but not in normal individuals. This bradykinin-induced bronchoconstriction is blocked by anticholinergic agents but not by antihistamines or cyclooxygenase inhibitors. Similarly, nasal challenge with bradykinin is followed by sneezing and glandular secretions in patients with allergic rhinitis, but not normal individuals or those with nonallergic, noninfectious perennial rhinitis.

**Cardiovascular System.** Infusion of bradykinin causes vasodilation and lowers blood pressure. Bradykinin causes vasodilation by activating its B2 receptor on endothelial cells, resulting in the generation of NO,
occurring within 1 h after dosing. Approximately 20% of patients treated women. Anaphylaxis has been reported in about 4% of treated patients, nasopharyngitis. Safety has not been tested in pregnant or nursing include headache, nausea, diarrhea, fever, injection site reactions, and 24-h period if the attack persists. The most common side effects (~3%–8% of patients) include headache, nausea, diarrhea, fever, injection site reactions, and nasopharyngitis. Safety has not been tested in pregnant or nursing women. Anaphylaxis has been reported in about 4% of treated patients, occurring within 1 h after dosing. Approximately 20% of patients treated with ecallantide develop antibodies to the drug and may be at a higher risk of hypersensitivity reactions on subsequent exposure. Ecallantide is currently being investigated as a potential treatment of other forms of angioedema (Zuraw et al., 2013).

**Bradykinin and the Effects of ACE Inhibitors**

The ACE inhibitors, widely used in the treatment of hypertension, con-gestive heart failure, and diabetic nephropathy, block the conversion of AngI to AngII and also block the degradation of bradykinin by ACE (see Figure 39–4 and Chapter 26). Numerous studies demonstrated that bradykinin contributes to many of the protective effects of ACE inhibitors (Heitsch, 2003; Madeddud et al., 2007). The search is on to find a suitable stable B1 agonist for clinical evaluation that provides cardiovascular benefit without pro-inflammatory effects.

A rare side effect of ACE inhibitors is angioedema, which is likely due to the inhibition of kinin metabolism by ACE (Zuraw et al., 2013). A common side effect of ACE inhibitors that may be related to enhanced kinin levels is a chronic, nonproductive cough that dissipates when the drug is stopped. Bradykinin may also contribute to the therapeu-tic effects of the AT1 receptor antagonists. During AT1 receptor block-ade, AngII signaling through the unopposed AT2 subtype receptor is enhanced, causing an increase in bradykinin concentrations, which has beneficial effects on cardiovascular and renal function (Padia and Carey, 2013). However, the increase in bradykinin levels is likely more modest than that achieved by ACE inhibitors, as reflected by the lower incidence of angioedema in patients taking AT1 receptor antagonists (Zuraw et al., 2013).

**Kinin Receptor Antagonists**

The selective B1 receptor antagonist icatibant has been approved in the E.U. and recently in the U.S. for treatment of acute episodes of swelling in patients more than 18 years of age with hereditary angioedema. It is administered by a healthcare professional, or self-administered by the patient after training, at a dose of 30 mg in 3 mL of solution by subcuta-neous injection in the abdomen. Additional doses may be administered at intervals of at least 6 h if the response is inadequate or symptoms recur, not to exceed three doses in any 24-h period. A common side effect experienced by most patients is a local reaction at the injection site (e.g., redness, bruising, swelling, burning, itching, etc.). A small percentage of patients experienced fever, elevated transaminase, dizziness, nausea, headache, or rash. Safety has not been tested in pregnant or nursing women. Although icatibant has the potential to attenuate the antihyper-tensive effects of ACE inhibitors, it is unclear if this is clinically signifi-cant, since patients taking ACE inhibitors were excluded from clinical trials with icatibant. Icatibant is currently being investigated as treatment of ACE inhibitor–induced angioedema, and initial results of small trials and individual case reports indicate that it is effective (Zuraw et al., 2013). Other forms of angioedema are under investigation for responsiveness to icatibant.

### Drug Facts for Your Personal Formulary: $H_1$ Antagonists

<table>
<thead>
<tr>
<th>Drugs</th>
<th>Therapeutic Uses</th>
<th>Clinical Pharmacology and Tips</th>
</tr>
</thead>
</table>
| **First-Generation Antihistamines: $H_1$ receptor inverse agonists**  
- Most have central and anticholinergic effects  
- Use with caution in children and in adults > 65 years of age |
| Doxepin  
- Tricyclic antidepressant  
- Insomnia  
- Pruritus (topical cream)  
- Pruritus (atopic dermatitis, eczema, lichen simplex) (cream) |  
- Causes significant sedation/drowsiness  
- Anticholinergic effects  
- Increased risk of suicidal thoughts (children, adolescents, and young adults) |
| Carboxinomine  
- Symptoms of allergic response |  
- Pronounced tendency to cause sedation  
- Significant anticholinergic effects  
- GI side effects are low  
- Carboxinomine and diphenhydramine: adjunct to epinephrine for anaphylaxis |
| Hydroxyzine  
- Pruritus  
- Sedation  
- Antianxiety  
- Atopic dermatitis  
- Antiemetic  
- Urticaria |  
- CNS depressant action may contribute to antipruritic effects |
| Cyclizine (discontinued in the U.S.; Meclizine not for use in children)  
- Motion sickness  
- Nausea/vomiting  
- Vertigo |  
- Antinausea properties due to prominent anticholinergic effects  
- Less likely to cause drowsiness than other first-generation drugs  
- Meclizine, most used, long effect (>8 h) |
| Promethazine  
- Antiemetic  
- Motion sickness  
- Pruritus  
- Sedation  
- Symptoms of allergic response (off-label use) |  
- Risk of fatal respiratory depression in children, especially < 2 years  
- May lower seizure threshold  
- Has local anesthetic activity  
- Most potent antihistamine antiemetic |
| Cyproheptadine  
- Allergic conjunctivitis  
- Allergic rhinitis  
- Anaphylaxis  
- Histamine-mediated angioedema  
- Pruritus, allergy  
- Vasomotor rhinitis  
- Urticaria  
- Dermatographism |  
- May increase appetite, cause weight gain  
- Has significant anticholinergic activity  
- Also blocks serotonin effects by antagonizing the $5HT_{1A}$ receptor |
| **Second-Generation Antihistamines: $H_1$ receptor inverse agonists**  
- Lack significant central and anticholinergic effects |
| Olopatadine (nasal and ophthalmic only)  
- Allergic conjunctivitis  
- Allergic rhinitis  
- Ocular pruritus  
- Rhinorrhea  
- Sneezing |  
- Approved for once-daily dosing  
- Eye drops may cause headaches in some  
- Nasal spray can cause epistaxis and nasal ulceration or septal perforation  
- Some increase in risk of somnolence with nasal spray  
- Nasal spray minor side effects include bitter taste and headache |
| Acrivastine (only marketed in combination with pseudoephedrine)  
- Allergic rhinitis  
- Nasal congestion  
- Allergic symptoms |  
- ~40% metabolized by CYPs, reducing potential for drug interactions  
- Somewhat higher risk of mild sedation than other second-generation drugs |
| Cetirizine  
- Allergic rhinitis  
- Atopic dermatitis (cetirizine)  
- Urticaria (chronic idiopathic) |  
- Somewhat higher risk of mild sedation than other second-generation drugs; more potent levocetirizine can be used at lower dose with less risk of sedation  
- Only ~30% (cetirizine) or ~1% (levocetirizine) metabolized by CYPs, reducing potential for drug interactions |
**Second-Generation Antihistamines: H<sub>1</sub> receptor inverse agonists • Lack significant central and anticholinergic effects (continued)**

**Bibliography**

Thurmond RL. The histamine H4 receptor: from orphan to the clinic. Front Pharmacol, 2015, 6:65.

Pulmonary pharmacology concerns understanding how drugs act on the lung and the pharmacological therapy of pulmonary diseases. Much of pulmonary pharmacology is concerned with the effects of drugs on the airways and the therapy of airway obstruction, particularly asthma and COPD, which are among the most common chronic diseases in the world. Both asthma and COPD are characterized by chronic inflammation of the airways, although there are marked differences in inflammatory mechanisms and response to therapy between these diseases (Barnes, 2008b; Postma and Rabe, 2015). This chapter discusses the pharmacotherapy of obstructive airways disease, particularly therapy with bronchodilators, which act mainly by reversing airway smooth muscle contraction, and anti-inflammatory drugs, which suppress the inflammatory response in the airways. This chapter focuses on the pulmonary pharmacology of β2 adrenergic agonists and corticosteroids; the basic pharmacology of these classes of agents is presented elsewhere (Chapters 12 and 46).

This chapter also discusses other drugs used to treat obstructive airway diseases, such as mucolytics and respiratory stimulants, and covers the drug therapy of cough, the most common respiratory symptom. Drugs used in the treatment of pulmonary hypertension (Chapter 31) or lung infections, including tuberculosis (Chapter 60), are covered elsewhere.

**Mechanisms of Asthma**

Asthma is a chronic inflammatory disease of the airways that is characterized by activation of mast cells, infiltration of eosinophils, T helper 2 (Th2) lymphocytes, and innate type 2 lymphocytes (ILC2) (Figure 40–1) (Barnes, 2011b; Lambrecht and Hammad, 2015). Mast cell activation by allergens and physical stimuli releases bronchoconstrictor mediators, such as histamine, LTD4, and prostaglandin D2, which cause bronchoconstriction, microvascular leakage, and plasma exudation. Increased numbers of mast cells in airway smooth muscle are a characteristic of asthma.

Many of the symptoms of asthma are due to airway smooth muscle contraction, and therefore bronchodilators are important as symptom relievers. Whether airway smooth muscle is intrinsically abnormal in asthma is not clear, but increased contractility of airway smooth muscle may contribute to airway hyperresponsiveness, the physiological hallmark of asthma.

The mechanism of chronic inflammation in asthma is still not well understood. It may initially be driven by allergen exposure, but it appears to become autonomous so that asthma is essentially incurable. The inflammation may be orchestrated by dendritic cells that regulate Th2 cells that drive eosinophilic inflammation and also IgE formation by B lymphocytes. Airway epithelium plays an important role through the release of multiple inflammatory mediators and through the release of growth factors in an attempt to repair the damage caused by inflammation. The inflammatory process in asthma is mediated through the release of more than 100 inflammatory mediators (Hall and Agrawal, 2014). Complex cytokine networks, including chemokines and growth factors, play important roles in orchestrating the inflammation process (Barnes, 2008a). Chronic inflammation may lead to structural changes (remodeling) in the airways, including an increase in the number and size of airway smooth muscle cells, blood vessels, and mucus-secreting cells. A characteristic
histological feature of asthma is collagen deposition (fibrosis) below the basement membrane of the airway epithelium (Figure 40–1). This appears to be the result of eosinophilic inflammation and is found even at the onset of asthmatic symptoms. The complex inflammation of asthma is suppressed by corticosteroids in most patients, but even if asthma is well controlled, the inflammation and symptoms return if corticosteroids are discontinued. Asthma usually starts in early childhood, then may disappear during adolescence and reappear in adulthood. It is characterized by variable airflow obstruction and typically shows a good therapeutic response to bronchodilators and corticosteroids. Asthma severity usually does not change, so that patients with mild asthma rarely progress to severe asthma and patients with severe asthma usually have this from the onset, although some patients, particularly with late-onset asthma, show a progressive loss of lung function like patients with COPD. Patients with severe asthma may have a pattern of inflammation more similar to COPD and are characterized by reduced responsiveness to corticosteroids (Trejo Bittar et al., 2015).

**Mechanisms of COPD**

Chronic obstructive pulmonary disease involves inflammation of the respiratory tract with a pattern that differs from that of asthma. In COPD, there is a predominance of neutrophils, macrophages, cytotoxic T lymphocytes (Tc1 cells), and T helper-17 (Th17) cells. The inflammation predominantly affects small airways, resulting in progressive small-airway narrowing and fibrosis (chronic obstructive bronchiolitis) and destruction of the lung parenchyma with destruction of the alveolar walls (emphysema) (Figure 40–2) (Barnes et al., 2015). These pathological changes result in airway closure on expiration, leading to air trapping and hyperinflation, particularly on exercise (dynamic hyperinflation). This accounts for shortness of breath on exertion and exercise limitation that are characteristic symptoms of COPD.

Bronchodilators reduce air trapping by dilating peripheral airways and are the mainstay of treatment in COPD. In contrast to asthma, the airflow obstruction of COPD tends to be progressive. The inflammation in the peripheral lung of patients with COPD is mediated by multiple inflammatory mediators and cytokines, although the pattern of mediators differs from that of asthma (Barnes, 2004). In contrast to asthma, the inflammation in patients with COPD is largely corticosteroid resistant, and there are currently no effective anti-inflammatory treatments. Many patients with COPD have comorbidities, including ischemic heart disease, hypertension, congestive heart failure, diabetes, osteoporosis, skeletal muscle wasting, depression, chronic renal disease, and anemia (Barnes and Celli, 2009). These diseases may occur together as part of multimorbidity, as diseases of accelerated aging with common pathogenetic mechanisms (Barnes, 2015).

**Routes of Drug Delivery to the Lungs**

Drugs may be delivered to the lungs by oral or parenteral routes and also by inhalation. The choice depends on the drug and on the respiratory disease.

**Inhaled Route**

Inhalation (Figure 40–3) is the preferred mode of delivery of many drugs with a direct effect on airways, particularly for asthma and COPD (Sanchis et al., 2013). It is the only way to deliver some drugs, such as cromolyn sodium and anticholinergic drugs, and is the preferred route of delivery for β2 agonists and corticosteroids to reduce systemic side effects. Antibiotics may be delivered by inhalation in patients with chronic respiratory sepsis (e.g., in cystic fibrosis). The major advantage of inhalation is the delivery of drug to the airways in doses that are effective with a much lower risk of systemic side effects. This is particularly important with the use of ICS, which largely avoids systemic side effects. In addition, inhaled bronchodilators have a more rapid onset of action than when taken orally.

**Particle Size**

The size of particles for inhalation is of critical importance in determining the site of deposition in the respiratory tract. The optimum size for particles to settle in the airways is 2- to 5-μm MMAD. Larger particles settle out in the upper airways, whereas smaller particles remain suspended and are therefore exhaled. There is increasing interest in delivering drugs to small airways, particularly in COPD and severe asthma (Usmani and...
**Figure 40–1** Cellular mechanisms of asthma. Myriad inflammatory cells are recruited and activated in the airways, where they release multiple inflammatory mediators, which can also arise from structural cells. These mediators lead to bronchoconstriction, plasma exudation and edema, vasodilation, mucus hypersecretion, and activation of sensory nerves. Chronic inflammation leads to structural changes, including subepithelial fibrosis (basement membrane thickening), airway smooth muscle hypertrophy and hyperplasia, angiogenesis, and hyperplasia of mucus-secreting cells.

Barnes, 2012). This involves delivering drug particles of about 1-μm MMAD, which is now possible using drugs formulated in HFA propellant.

**Pharmacokinetics**

Of the total drug delivered, only 10%–20% enters the lower airways with a conventional pMDI. Drugs are absorbed from the airway lumen and have direct effects on target cells of the airway. Drugs may also be absorbed into the bronchial circulation and then distributed to more peripheral airways. Drugs with higher molecular weights tend to be retained to a greater extent in the airways. Nevertheless, several drugs have greater therapeutic efficacy when given by the inhaled route. The ICS ciclesonide is a prodrug activated by esterases in the respiratory tract to the active principle des-ciclesonide. More extensive pulmonary distribution of a drug with a smaller MMAD increases alveolar deposition and thus is likely to increase absorption from the lungs into the general circulation, resulting in more systemic side effects. Thus, although HFA pMDIs deliver more ICS to smaller airways, there is also increased systemic absorption, so that the therapeutic ratio may not be changed.

**Figure 40–2** Cellular mechanisms in COPD. Cigarette smoke and other irritants activate epithelial cells and macrophages in the lung to release mediators that attract circulating inflammatory cells, including monocytes (which differentiate to macrophages within the lung), neutrophils, and T lymphocytes (T<sub>1</sub>, T<sub>17</sub>, and Th17 cells). Fibrogenic factors released from epithelial cells and macrophages lead to fibrosis of small airways. Release of proteases results in alveolar wall destruction (emphysema) and mucus hypersecretion (chronic bronchitis).
Corticosteroids may have to be given orally for parenchymal lung diseases (e.g., in interstitial lung diseases).

**Parenteral Route**
The intravenous route should be reserved for delivery of drugs in the severely ill patient who is unable to absorb drugs from the GI tract. Side effects are generally frequent due to the high plasma concentrations.

**Bronchodilators**
Bronchodilator drugs relax constricted airway smooth muscle in vitro and cause immediate reversal of airway obstruction in asthma in vivo (Cazzola et al., 2012). They also prevent bronchoconstriction (and thereby provide bronchoprotection). Three main classes of bronchodilator are in current clinical use:

- β2 Adrenergic agonists (sympathomimetics)
- Theophylline (a methylxanthine)
- Anticholinergic agents (muscarinic receptor antagonists)

Drugs such as **cromolyn sodium**, which prevent bronchoconstriction, have no direct bronchodilator action and are ineffective once bronchoconstriction has occurred. **Anti-LTs** (LT receptor antagonists and 5′-lipoxygenase inhibitors) have a small bronchodilator effect in some asthmatic patients and appear to prevent bronchoconstriction. *Corticosteroids*, although gradually improving airway obstruction, have no direct effect on contraction of airway smooth muscle and are not therefore considered to be bronchodilators.

**β2 Adrenergic Agonists**
Inhaled β2 agonists are the bronchodilator treatment of choice in asthma because they are the most effective bronchodilators and have minimal side effects when used correctly. Systemic, short-acting, and nonselective β agonists, such as isoproterenol (isoprenaline) or metaproterenol, should only be used as a last resort.

**Chemistry**
The development of β2 agonists is based on substitutions in the catecholamine structure of norepinephrine and epinephrine (see Chapters 8 and 12). The catechol ring consists of hydroxyl groups in the 3 and 4 positions of the benzene ring. Norepinephrine differs from epinephrine only in the terminal amine group; in general, further modification at this site confers β receptor selectivity. Many β2-selective agonists have now been introduced, and although there may be differences in potency, there are no clinically significant differences in selectivity. Inhaled β2-selective drugs in current clinical use have a similar duration of action (3–6 h).
The inhaled LABAs, salmeterol and formoterol, have a much longer duration of effect, providing bronchodilation and bronchoprotection for more than 12 h (Cazzola et al., 2013b). Formoterol has a bulky substituent in the aliphaticchain and has moderate lipophilicity, which appears to keep the drug in the membrane close to the receptor, so it behaves as a slow-release drug. Salmeterol has a long aliphatic chain, and its long duration may be due to binding within the receptor binding cleft (“exosite”) that anchors the drug in the binding cleft. Once-daily β₂ agonists, such as indacaterol, vilanterol, and olodaterol, with a duration of action more than 24 h have now been developed.

**Mode of Action**

Occupation of β₂ receptors by agonists results in the activation of the Gₛ-adenyl cyclase-cAMP-PKA pathway, resulting in phosphorylative events leading to bronchial smooth muscle relaxation (Figure 40–4). β₂ Receptors are localized to several different airway cells, where they may have additional effects. β₂ Agonists may cause bronchodilation also indirectly by inhibiting the release of bronchoconstrictor mediators from inflammatory cells and of bronchoconstrictor neurotransmitters from airway nerves. These mechanisms include the following:

- Prevention of mediator release from isolated human lung mast cells (via β₂ receptors)
- Prevention of microvascular leakage and thus the development of bronchial mucosal edema after exposure to mediators, such as histamine, LTD₄, and prostaglandin D₂
- Increase in mucus secretion from submucosal glands and ion transport across airway epithelium (may enhance mucociliary clearance, reversing defective clearance found in asthma)
- Reduction in neurotransmission in human airway cholinergic nerves by an action at presynaptic β₂ receptors to inhibit ACh release

Although these additional effects of β₂ agonists may be relevant to the prophylactic use of these drugs against various challenges, their rapid bronchodilator action is probably attributable to a direct effect on smooth muscle of all airways.

**Anti-inflammatory Effects**

Whether β₂ agonists have anti-inflammatory effects in asthma is controversial. The inhibitory effects of β₂ agonists on mast cell mediator release and microvascular leakage are clearly anti-inflammatory, suggesting that β₂ agonists may modify acute inflammation. However, β₂ agonists do not appear to have a significant inhibitory effect on the chronic inflammation of asthmatic airways, which is suppressed by corticosteroids. This has now been confirmed by several biopsy and bronchoalveolar lavage studies in patients with asthma who are taking regular β₂ agonists (including LABAs), that demonstrated no significant reduction in the number or activation in inflammatory cells in the airways, in contrast to resolution of the inflammation that occurs with ICS. This may be related to the fact that effects of β₂ agonists on macrophages, eosinophils, and lymphocytes are rapidly desensitized.

**Clinical Use**

**Short-Acting β₂ Agonists.** Inhaled SABAs are the most widely used and effective bronchodilators in the treatment of asthma due to their functional antagonism of bronchoconstriction. When inhaled from pMDIs or DPIs, they are convenient, easy to use, rapid in onset, and without significant systemic side effects. These agents are effective in protecting against various asthma triggers, such as exercise, cold air, and allergens. SABAs are the bronchodilators of choice in treating acute severe asthma. The nebulized route of administration is easier and safer than intravenous administration and just as effective. Inhalation is preferable to oral administration because systemic side effects are less. SABAs, such as albuterol, should be used “as required” by symptoms and not on a regular basis in the treatment of mild asthma; increased use indicates the need for more anti-inflammatory therapy.

Oral β₂ agonists are occasionally indicated as an additional bronchodilator. Slow-release preparations (e.g., slow-release albuterol and balmuterol [not available in the U.S.]) may be indicated in nocturnal asthma; however, these agents have an increased risk of side effects. Several SABAs are available; they are resistant to uptake and enzymatic degradation by COMT and MAO; all are usable by inhalation and orally, have a similar duration of action (~3–4 h; less in severe asthma), and similar side effects. Differences in β₂ receptor selectivity have been claimed but are not clinically important. Drugs in clinical use include albuterol (salbutamol), levalbuterol, metaproterenol, terbutaline, pirbuterol, as well as several not available in the U.S. (fenoterol, tulobuterol, and rimiterol).

**Long-Acting Inhaled β₂ Agonists.** The LABAs salmeterol, formoterol, and arformoterol have proved to be a significant advance in asthma and COPD therapy. These drugs have a bronchodilator action of more than 12 h and also protect against bronchoconstriction for a similar period.
(Cazzola et al., 2013b). They improve asthma control (when given twice daily) compared with regular treatment with SABAs (four to six times daily). Once-daily LABAs, such as indacaterol, vilanterol, and olodaterol, with a duration of over 24 h have now been developed and are more effective in patients with COPD than twice-daily LABAs and more frequent SABAs.

Tolerance to the bronchodilator effect of formoterol and the bronchoprotective effects of formoterol and salmeterol have been demonstrated but is of doubtful clinical significance. Although both formoterol and salmeterol have a similar duration of effect in clinical studies, there are differences. Formoterol has a more rapid onset of action and is an almost-full agonist, whereas salmeterol is a partial agonist with a slower onset of action. These differences might confer a theoretical advantage for formoterol in more severe asthma, whereas it may also make it more likely to induce tolerance. However, no significant clinical differences between salmeterol and formoterol have been found in the treatment of patients with severe asthma (Nightingale et al., 2002).

In COPD, LABAs are effective bronchodilators that may be used alone or in combination with anticholinergics or ICs. LABAs improve symptoms and exercise tolerance by reducing both air trapping and exacerbations. In patients with asthma, LABAs should never be used alone because they do not treat the underlying chronic inflammation, and this may increase the risk of life-threatening and fatal asthma exacerbations; rather, LABAs should always be used in combination with an ICS in a fixed-dose combination inhaler. LABAs are an effective add-on therapy to ICs and are more effective than increasing the dose of an ICS when asthma is not controlled at low doses.

**Combination Inhalers.** Combination inhalers that contain a LABA and a corticosteroid (e.g., fluticasone/salmeterol, budesonide/formoterol) are now widely used in the treatment of asthma and COPD. In asthma, combining a LABA with a corticosteroid offers complementary synergistic actions (Barnes, 2002). The combination inhaler is more convenient for patients, simplifies therapy, and improves adherence with the ICS. Also, delivering the two drugs in the same inhaler ensures they are delivered simultaneously to the same cells in the airways, allowing the beneficial molecular interactions between LABAs and corticosteroids to occur. Combination inhalers are now the preferred therapy for patients with persistent asthma. These combination inhalers are also more effective in patients with COPD than a LABA and an ICS alone, but the mechanisms accounting for this beneficial interaction are less well understood than in patients with asthma.

**Steroselective β2 Agonists.** Albuterol is a racemic mixture of active R- and inactive S-isomers. Although R-albuterol (levalbuterol) was more potent than racemic R/S-albuterol in some studies, careful dose responses showed no advantage in terms of efficacy and no evidence that the S-albuterol is detrimental in asthmatic patients (Lotvall et al., 2001). Because levalbuterol is usually more expensive than normally used racemic albuterol, this therapy has no clear clinical advantage. Steroselective formoterol (R,R-formoterol, arformoterol) has now been developed as a nebulized solution but also appears to offer no clinical advantage over racemic formoterol in patients with COPD (Loh et al., 2015).

**β2 Receptor Polymorphisms.** Several single-nucleotide polymorphisms and haplotypes of the human ADRB2, which affect the structure of β2 receptors, have been described. The common variants are Gly9Arg and Gin11Glu, which have in vitro effects on receptor desensitization, but clinical studies have shown inconsistent effects on the bronchodilator responses to SABAs and LABAs (Hawkins et al., 2008). Some studies have shown that patients with the common homozygous Arg11Arg variant have more frequent adverse effects and a poorer response to SABAs than heterozygotes or Gin11Gly homozygotes, but overall these differences are small, and there appears to be no clinical value in measuring ADRB2 genotype. No differences have been found with responses to LABA between these genotypes (Bleecker et al., 2007).

**Side Effects.** Unwanted effects are dose related and due to stimulation of extrapulmonary β2 receptors (Table 40–1 and Chapter 12). Side effects are not common with inhaled therapy but quite common with oral or intravenous administration.

- **Muscle tremor** (direct effect on skeletal muscle β2 receptors)
- **Tachycardia** (direct effect on atrial β1 receptors, reflex effect from increased peripheral vasodilation via β2 receptors)
- **Hypokalemia** (direct β2 effect on skeletal muscle uptake of K+)
- **Restlessness**
- **Hypoxemia** (T V/Q mismatch due to reversal of hypoxic pulmonary vasoconstriction)
- **Metabolic effects** (↑ FFA, glucose, lactate, pyruvate, insulin)

**TABLE 40–1 SIDE EFFECTS OF β2 AGONISTS**

- **Muscle tremor** (direct effect on skeletal muscle β2 receptors)
- **Tachycardia** (direct effect on atrial β1 receptors, reflex effect from increased peripheral vasodilation via β2 receptors)
- **Hypokalemia** (direct β2 effect on skeletal muscle uptake of K+)
- **Restlessness**
- **Hypoxemia** (T V/Q mismatch due to reversal of hypoxic pulmonary vasoconstriction)
- **Metabolic effects** (↑ FFA, glucose, lactate, pyruvate, insulin)

**Tolerance.** Continuous treatment with an agonist often leads to tolerance, which may be due to downregulation of the receptor (Chapter 12). Tolerance of nonairway β2 receptor–mediated responses, such as tremor and cardiovascular and metabolic responses, is readily induced in normal and asthmatic subjects. In asthmatic patients, tolerance to the bronchodilator effects of β2 agonists has not usually been found. However, tolerance develops to the bronchoprotective effects of β2 agonists, and this is more marked with indirect bronchoconstrictors that activate mast cells (e.g., adenosine, allergen, and exercise) than with direct bronchoconstrictors, such as histamine and methacholine. The reason for the relative resistance of airway smooth muscle β2 receptors to desensitization remains uncertain but may reflect the large receptor reserve: More than 90% of β2 receptors may be lost without any reduction in the relaxation response. The high level of ADRB2 expression in airway smooth muscle compared with peripheral lung may also contribute to the resistance to tolerance because a high rate of β2 receptor synthesis is likely. In addition, the expression of GRK2, which phosphorylates and inactivates occupied β2 receptors, is very low in airway smooth muscle (Penn et al., 1998). By contrast, there is no receptor reserve in inflammatory cells, GRK2 expression is high, and tolerance to β2 agonists rapidly develops at these sites.

Experimental studies have shown that corticosteroids prevent the development of tolerance in airway smooth muscle and prevent and reverse the fall in pulmonary β receptor density (Mak et al., 1995). However, ICs fail to prevent the tolerance to the bronchoprotective effect of inhaled β2 agonists, possibly because they do not reach airway smooth muscle in a high enough concentration.
Long-Term Safety. Because of a possible relationship between adrenergic drug therapy and the rise in asthma deaths in several countries during the early 1960s, doubts were cast on the long-term safety of β agonists. A particular β agonist, fenoterol, was linked to the rise in asthma deaths in New Zealand in the early 1990s because significantly more of the fatal cases were prescribed fenoterol than the case-matched control patients (Beasley et al., 1999). An epidemiological study examining the links between drugs prescribed for asthma and death or near death from asthma attacks found a marked increase in the risk of death with high doses of all inhaled β agonists. The risk was greater with fenoterol, but when the dose is adjusted to the equivalent dose for albuterol, there is no significant difference in the risk for these two drugs.

The link between high β agonist usage and increased asthma mortality does not prove a causal association because patients with more severe and poorly controlled asthma, who are more likely to have an increased risk of fatal attacks, are more likely to be using higher doses of β agonist inhalers and less likely to be using effective anti-inflammatory treatment. Indeed, in the patients who used regular inhaled steroids, there was a significant reduction in risk of death.

Regular use of inhaled β agonists has also been linked to increased asthma morbidity. Regular use of fenoterol was associated with worse asthma control and a small increase in airway hyperresponsiveness compared with patients using fenoterol “on demand” for symptom control over a 6-month period (Sears, 2002). However, this was not found in a study with regular albuterol (Dennis et al., 2000). There is some evidence that regular inhaled β agonists may increase allergen-induced asthma and sputum eosinophilia (Gauvreau et al., 1997).

SARAs should only be used on demand for symptom control, and if they are required frequently (more than three times weekly), an ICS is needed.

The safety of LABAs in asthma remains controversial. A large study of the safety of salmeterol showed an excess of respiratory deaths and near deaths in patients prescribed salmeterol, but these deaths occurred mainly in African Americans living in inner cities who were not taking ICSs (Nelson and Dorinsky, 2006). Similar data have also raised concerns about formoterol. However, concomitant treatment with an ICS appears to obviate such risk, so it is recommended that LABAs should only be used when ICSs are also prescribed (preferably in the form of a combination inhaler so that the LABAs can never be taken without the ICSs) (Cates et al., 2014). All LABAs approved in the U.S. carry a black-box warning cautioning against overdose. There are fewer safety concerns with LABA use in COPD. No major adverse effects were reported in several large and prolonged studies and no evidence of cardiovascular problems (Kew et al., 2013).

Future Developments
The β agonists will continue to be the bronchodilators of choice for asthma because they are effective in all patients and have few or no side effects when used in low doses. When used as required for symptom control, inhaled β agonists appear safe. Use of large doses of inhaled β agonists indicates poor asthma control; such patients should be assessed and appropriate controller medication used. LABAs are a useful option for long-term control in asthma and COPD. In patients with asthma, LABAs should probably only be used in a fixed combination with an ICS to prevent the potential danger associated with LABAs alone. There is little advantage to be gained by improving β2 receptor selectivity because most of the side effects of these agents are due to β2 receptor stimulation (muscle tremor, tachycardia, hypokalemia). Once-daily inhaled β agonists are useful in patients with COPD and may have additive effects with LAMAs.

Methylxanthines
Methylxanthines, such as theophylline, which are related to caffeine, have been used in the treatment of asthma since 1930, and theophylline is still widely used in developing countries because it is inexpensive. Theophylline became more useful with the introduction of reliable slow-release preparations. However, inhaled β agonists are far more effective as bronchodilators, and ICSs have a greater anti-inflammatory effect. In patients with severe asthma and COPD, it still remains a useful drug as an add-on therapy (Barnes, 2013c).

Chemistry
Theophylline is a methylxanthine similar in structure to the common dietary xanthines caffeine and theobromine. Several substituted derivatives have been synthesized, but only two appear to have any advantage over theophylline: Enprofylline is a more potent bronchodilator, and may have fewer toxic effects because it does not antagonize adenosine receptors; doxofylline, a novel methylxanthine available in some countries, has an inhibitory effect on PDEs similar to that of theophylline but is less active as an adenosine antagonist and has a more favorable side-effect profile (Akrum et al., 2012). Many salts of theophylline have also been marketed; the most common is aminophylline. Other salts do not have any advantage. Theophylline remains the major methylxanthine in clinical use.

Mechanism of Action
The mechanisms of action of theophylline are still uncertain. In addition to its bronchodilator action, theophylline has many nonbronchodilator effects that may be relevant to its effects in asthma and COPD (Figure 40–5). Several molecular mechanisms of action have been proposed:

- **Inhibition of PDEs.** Theophylline is a nonselective PDE inhibitor, but the degree of inhibition is relatively minimal at concentrations of theophylline that are within the therapeutic range. PDE inhibition and the concomitant elevation of cellular cAMP and cyclic GMP likely account for the bronchodilator action of theophylline. Several isoenzyme families of PDE have now been recognized, and those important in smooth muscle relaxation include PDE3, PDE4, and PDE5.

- **Adenosine receptor antagonism.** Theophylline antagonizes adenosine receptors at therapeutic concentrations. Adenosine causes bronchoconstriction in airways from asthmatic patients by releasing histamine and LTs. Antagonism of A2 receptors may be responsible for serious side effects, including cardiac arrhythmias and seizures.

- **Interleukin 10 release.** IL-10 has a broad spectrum of anti-inflammatory effects, and there is evidence that its secretion is reduced in asthma. IL-10 release is increased by theophylline, and this effect may be mediated via inhibition of PDE activities, although this has not been seen at the low doses that are effective in asthma.

- **Effects on gene transcription.** Theophylline prevents the translocation of the pro-inflammatory transcription factor NF-κB into the nucleus, potentially reducing the expression of inflammatory genes in asthma and COPD (Ichiyama et al., 2001). However, these effects are seen at high concentrations and may be mediated by inhibition of PDE.

- **Effects on apoptosis.** Prolonged survival of granulocytes due to a reduction in apoptosis may be important in perpetuating chronic inflammation in asthma (eosinophils) and COPD (neutrophils). Theophylline promotes apoptosis in eosinophils and neutrophils in vitro. This is associated with a reduction in the antiapoptotic protein Bcl-2 (Chung et al., 2000). This effect is not mediated via PDE inhibition, but in neutrophils may be mediated by antagonism of adenosine A2 receptors (Yasui et al., 2000). Theophylline also induces apoptosis in T lymphocytes via PDE inhibition.

- **Histone deacetylase activation.** Recruitment of HDAC2 by GRs switches off inflammatory genes. Therapeutic concentrations of theophylline activate HDAC, thereby enhancing the anti-inflammatory effects of corticosteroids (Cosio et al., 2004). This mechanism appears to be mediated by inhibition of PI3-kinase-δ, which is activated by oxidative stress (To et al., 2010).
Nonbronchodilator Effects
Theophylline has clinical benefit in asthma and COPD at plasma concentrations less than 10 mg/L, sufficiently low that such effects are unlikely to be explained by theophylline's bronchodilator action. There is increasing evidence that theophylline has anti-inflammatory effects in asthma (Barnes, 2013c). In patients with mild asthma, chronic oral treatment with theophylline inhibits the late response to inhaled allergen and reduces infiltration of eosinophils and CD4+ lymphocytes into the airways after allergen challenge (Lim et al., 2001). In patients with COPD, theophylline reduces the total number and proportion of neutrophils in induced sputum, the concentration of IL-8, and neutrophil chemotactic responses (Culpitt et al., 2002). Theophylline withdrawal in patients with COPD results in worsening of disease. In vitro theophylline is able to increase responsiveness to corticosteroids and to reverse corticosteroid resistance in cells from subjects with COPD (Cosio et al., 2004).

Pharmacokinetics and Metabolism
Theophylline has antiasthma effects other than bronchodilation below 10 mg/L, so the therapeutic range is now taken as 5–15 mg/L. The dose of theophylline required to give these therapeutic concentrations varies among subjects, largely because of differences in clearances of the drug. In addition, there may be differences in bronchodilator response to theophylline; furthermore, with acute bronchoconstriction, higher concentrations may be required to produce bronchodilation. Theophylline is rapidly and completely absorbed, but there are large interindividual variations in clearance due to differences in hepatic metabolism. Theophylline is metabolized in the liver, mainly by CYP1A2; myriad factors influence hepatic metabolism and clearance of of theophylline (see Table 40–2).

Because of these variations in clearance, individualization of theophylline dosage is required, and plasma concentrations should be measured 4 h after the last dose with slow-release preparations when steady state has been achieved. There is no significant circadian variation in theophylline metabolism, although there may be delayed absorption at night related to supine posture.

Preparations and Routes of Administration
Intravenous aminophylline, an ethylene diamine ester of theophylline that is water soluble, has been used for many years in the treatment of acute severe asthma. The recommended dose is 6 mg/kg given intravenously over 20–30 min, followed by a maintenance dose of 0.5 mg/kg per hour. If the patient is already taking theophylline, or there are any factors that decrease clearance, these doses should be halved and the plasma level checked more frequently. Nebulized β2 agonists are now preferred over intravenous aminophylline for acute exacerbations of asthma and COPD.

Oral immediate-release theophylline tablets or elixirs, which are rapidly absorbed, give wide fluctuations in plasma levels and are not recommended. Several sustained-release preparations are now available that are absorbed at a constant rate and provide steady plasma concentrations over a 12- to 24-h period. Both slow-release aminophylline and theophylline are available and are equally effective (although the ethylene diamine component of aminophylline has been implicated in allergic reactions). For continuous treatment, twice-daily therapy (~8 mg/kg, twice daily) is needed. For nocturnal asthma, a single dose of slow-release theophylline at night is often effective. Once optimal doses have been determined, routine monitoring of plasma concentrations is usually not necessary unless a change in clearance is suspected or evidence of toxicity emerges.

Clinical Use
In patients with acute asthma, intravenous aminophylline is less effective than nebulized β2 agonists and should therefore be reserved for those patients who fail to respond to, or are intolerant of, β2 agonists. Theophylline should not be added routinely to nebulized β2 agonists because it does not increase the bronchodilator response and may increase their side effects. Theophylline has been used as a controller in the management of mild persistent asthma, although it is usually found to be less effective than low doses of ICSs. Addition of low-dose theophylline to an ICS in patients who are not adequately controlled provides better symptom control and lung function than doubling the dose of inhaled steroid (Lim et al., 2001). LABAs are more effective as an add-on therapy, but theophylline is

considerably less expensive and may be the only affordable add-on treatment when the costs of medication are limiting. Theophylline is still used as a bronchodilator in COPD, but inhaled anticholinergics and β2 agonists are preferred. Theophylline tends to be added to these inhaled bronchodilators in patients with more severe disease and has been shown to give additional clinical improvement when added to a LABA.

**Side Effects**

Unwanted effects of theophylline are usually related to plasma concentrations and tend to occur at C_{ss} greater than 15 mg/L. The most common side effects are headache, nausea, and vomiting (due to inhibition of PDE4), abdominal discomfort, and restlessness (Table 40–3). There may also be increased acid secretion (due to PDE inhibition) and diuresis (due to inhibition of adenosine A1 receptors). Theophylline may lead to behavioral disturbance and learning difficulties in schoolchildren. At high concentrations, cardiac arrhythmias may occur as a consequence of inhibition of cardiac PDE3 and antagonism of cardiac A1 receptors. At very high concentrations, seizures may occur due to central A1 receptor antagonism. Use of low doses of theophylline, targeting plasma concentrations of 5–10 mg/L, largely avoids side effects and drug interactions.

**Summary and Future Developments**

Theophylline use has been declining, partly because of the problems with side effects, but mainly because more effective therapy with β2 agonists and LAMs have been introduced. Oral theophylline remains a useful add-on treatment in some patients with difficult asthma and appears to have effects beyond those provided by steroids. Rapid-release theophylline preparations are the only affordable antiasthma medication in some developing countries. There is increasing evidence that theophylline has some antiasthma effect at doses that are lower than those needed for bronchodilation, and plasma levels of 5–15 mg/L are recommended.

**Muscarinic Cholinergic Antagonists**

The basic pharmacology of the antimuscarinic agents is presented in Chapter 9.

A, adenosine.

**Mode of Action**

As competitive antagonists of endogenous ACh at muscarinic receptors, these agents inhibit the direct constrictor effect on bronchial smooth muscle mediated via the M1, Gp, PLC-IP, Ca2+ pathway (see Chapters 3 and 9). The efficacy stems from the role played by the parasympathetic nervous system in regulating bronchomotor tone. The effects of ACh on the respiratory system include bronchoconstriction and tracheobronchial mucus secretion. Thus, antimuscarinic drugs antagonize these effects of ACh, resulting in bronchodilation and reduced mucus secretion. Acetylcholine may also be released from other airway cells, including epithelial cells (Wessler and Kirkpatrick, 2008). The synthesis of ACh in epithelial cells is increased by inflammatory stimuli (such as TNF-α), which increase the expression of choline acetyltransferase, which could contribute to cholinergic effects in airway diseases. Muscarinic receptors are expressed in airway smooth muscle of small airways that do not appear to be significantly innervated by cholinergic nerves; these receptors may be a mechanism of cholinergic narrowing in peripheral airways that could be relevant in COPD, responding to locally synthesized, nonneuronal ACh.

Myriad mechanical, chemical, and immunological stimuli elicit reflex bronchoconstriction via vagal pathways, and cholinergic pathways may play an important role in regulating acute bronchomotor responses in animals. Anticholinergic drugs will only inhibit reflex ACh-mediated bronchoconstriction and have no blocking effect on the direct effects of inflammatory mediators, such as histamine and LTD4, on bronchial smooth muscle. Furthermore, cholinergic antagonists probably have little or no effect on mast cells, microvascular leak, or the chronic inflammatory response.

**Clinical Use**

In asthmatic patients, anticholinergic drugs are less effective as bronchodilators than β2 agonists and offer less-efficient protection against bronchial challenges. Anticholinergics are currently used as an additional bronchodilator in asthmatic patients not controlled on a LABA. Nebulized anticholinergic drugs are effective in acute severe asthma but less effective than β2 agonists. In the acute and chronic treatment of asthma, anticholinergic drugs may have an additive effect with β2 agonists and should therefore be considered when control of asthma is not adequate with nebulized β2 agonists. A muscarinic antagonist should be considered when there are problems with theophylline or when inhaled β2 agonists cause a troublesome tremor in elderly patients.

In COPD, anticholinergic drugs may be as effective as or even superior to β2 agonists. Their relatively greater effect in COPD than in asthma may be explained by an inhibitory effect on vagal tone, which, although not necessarily increased in COPD, may be the only reversible element of airway obstruction and one that is exaggerated by geometric factors in the narrowed airways of patients with COPD (Figure 40–6). Anticholinergic drugs reduce air trapping and improve exercise tolerance in patients with COPD.

**Therapeutic Choices**

The SAMA ipratropium bromide is available as a pMDI and nebulized preparation. The onset of bronchodilation is relatively slow and is usually maximal 30–60 min after inhalation but may persist for 6–8 h. It is usually given by MDI three or four times daily on a regular basis, rather than intermittently for symptom relief, in view of its slow onset of action, but has now been replaced by LAMAs, such as tiotropium bromide.

**Long-Acting Muscarinic Antagonists**

Several LAMAs have now been developed from the treatment of COPD and, more recently, severe asthma. Tiotropium bromide is a long-acting anticholinergic drug that is suitable for once-daily dosing as a DPI (Spiriva) or via a soft mist minibulizer device and was more effective than ipratropium four times daily in several studies; it also significantly reduces exacerbations (Cheyne et al., 2015). Tiotropium binds to all muscarinic receptor subtypes but dissociates slowly from M1 and M3 receptors, giving it a degree of kinetic receptor selectivity for these receptors compared with M2 receptors, from which it dissociates more rapidly. Thus, compared with ipratropium, tiotropium is less likely to antagonize M2-mediated inhibition of ACh release (the resulting increase in ACh could counteract the

**History**

Datura stramonium (jimson weed) and related species of the nightshade family contain a mixture of muscarinic antagonists (atropine, hyoscyamine, and scopolamine) and were smoked for relief of asthma two centuries ago. Subsequently, the purified plant alkaloid atropine was introduced for treating asthma. Due to the significant side effects of atropine, particularly drying of secretions, less-soluble quaternary compounds, such as atropine methylsulfate and ipratropium bromide, have been developed. These compounds are topically active and are not significantly absorbed from the respiratory or GI tracts.
blockade of M2 receptor–mediated bronchoconstriction (Chapter 9). Over a 4-year period, tiotropium improved lung function and health status and reduced exacerbations and all-cause mortality, although there was no effect on disease progression (Tashkin et al., 2008).

Glycopyrronium bromide and umeclidinium bromide are also once-daily LAMAs with very similar clinical effects to tiotropium, whereas aclidinium bromide has to be given twice daily (Cazzola et al., 2013a). LAMAs are now becoming the bronchodilators of choice for patients with COPD. LAMAs are also effective as additional bronchodilators in patient with asthma not adequately controlled with maximal ICS/LABA therapy, although not all patients respond (Kerstjens et al., 2015).

**Combination Inhalers**

There are additive bronchodilator effects between anticholinergics and β2 agonists in patients with COPD, which has led to the development of fixed-dose combinations. SABA/SAMA combinations, such as albuterol/ipratropium, are popular. Several studies have demonstrated additive effects of these two drugs, thus providing an advantage over increasing the dose of β2 agonist in patients who have side effects.

LABA/LAMA dual combination inhalers have also been developed, including indacaterol/glycopyrronium, vilanterol/umeclidinium bromide, olodaterol/tiotropium bromide (all once daily), and formoterol/glycopyrronium bromide, forntomterol/aclidinium bromide (twice daily), which all show beneficial effects on lung function compared with either LABA or LAMA alone, although they may not be clearly beneficial in terms of reducing exacerbations (Calzeta et al., 2016).

**Adverse Effects**

Inhaled anticholinergic drugs are generally well tolerated. On stopping inhaled anticholinergics, a small rebound increase in airway responsiveness has been described. Systemic side effects after SAMA or LAMA are uncommon during normal clinical use because there is little systemic absorption. Because cholinergic agonists can stimulate mucus secretion, there has been concern that anticholinergics may reduce secretion and lead to more viscus mucus. However, ipratropium bromide and tiotropium bromide, even in high doses, have no detectable effect on mucociliary clearance in either normal subjects or in patients with airway disease. A significant unwanted effect is the unpleasant bitter taste of inhaled ipratropium, which may contribute to poor compliance. Nebulized ipratropium bromide may precipitate glaucoma in elderly patients due to a direct effect of the nebulized drug on the eye. This may be prevented by nebulization with a mouthpiece rather than a face mask.

Reports of paradoxical bronchoconstriction with ipratropium bromide, particularly when given by nebulizer, were largely explained as effects of the hypotonic nebulizer solution and by antibacterial additives, such as benzalkonium chloride and EDTA. This problem has not been described with tiotropium bromide or other LAMAs. Occasionally, bronchoconstriction may occur with ipratropium bromide given by MDI. It is possible that this is due to blockade of prejunctional M2 receptors on airway cholinergic nerves that normally inhibit ACh release.

LAMAs cause dryness of the mouth in 10%–15% of patients, but this usually disappears during continued therapy. Urinary retention is occasionally seen in elderly patients.

**Future Developments**

The LABA/LAMA fixed-combination inhalers are likely to become the bronchodilators of choice in patients with COPD, and LAMAs are added to ICS/LABA combinations in severe asthma. Some triple inhalers that have the ICS/LABA/LAMA combination, such as budesonide/formoterol/glycopyrronium, mometasone/indacaterol/glycopyrronium, and fluticasone furoate/umeclidinium/vilanterol, are in development for use in patients with severe asthma and asthma–COPD overlap. Dual-action drugs that are both muscarinic antagonists and β2 agonist are also in clinical development, but it has proved difficult to balance the β2 agonist and anticholinergic activities (Ray and Alcaraz, 2009).

**Novel Classes of Bronchodilator**

Currently, the most effective bronchodilators are LABAs for asthma and a LAMA for COPD. Inventing new classes of bronchodilator has been difficult; several agents have had problems with vasodilator side effects because they relax vascular smooth muscle to a greater extent than airway smooth muscle. Nonetheless, there are several classes of bronchodilators under development, as described next.

**Magnesium Sulfate**

Magnesium sulfate (MgSO4) is useful as an additional bronchodilator in children and adults with acute severe asthma. Intravenous or nebulized MgSO4 benefits adults and children with severe exacerbations (FEV1 < 30% of predicted value), giving improvement in lung function when added to nebulized β2 agonist and a reduction in hospital admissions (Kew et al., 2014). The treatment is cheap and well tolerated, although the clinical benefit appears small. Side effects include flushing and nausea but are usually minor. Magnesium sulfate appears to act as a bronchodilator and may reduce cytosolic Ca2+ concentrations in airway smooth muscle cells. The concentration of magnesium is lower in serum and erythrocytes of asthmatic patients than in normal controls and correlates with airway hyper-responsiveness, although the improvement in acute severe asthma after magnesium does not correlate with plasma concentrations. The effects of intravenous MgSO4 in COPD are minimal, and there are too few studies to make any firm recommendation (Shivathan and Rajapakse, 2014).

**Potassium Channel Openers**

The K+ channel openers such as cromakalim or levocromakalim (the levo-isomer of cromakalim) open ATP-dependent K+ channels in smooth muscle, leading to membrane hyperpolarization and relaxation of airway smooth muscle. This suggests that K+ channel activators may be useful as bronchodilators (Pelaia et al., 2002). Clinical studies in asthma, however, have been disappointing, with no bronchodilation or protection against bronchoconstrictor challenges. The cardiovascular side effects of these drugs (postural hypotension, flushing) limit the oral dose; furthermore, inhaled formulations are problematic. New developments include K+ channel openers that open Ca2+-activated large conductance K+ channels (maxi-K channels) that are also opened by β2 agonists; these drugs may be better tolerated. Maxi-K channel openers also inhibit mucus secretion and...
cough, and they may be of particular value in the treatment of COPD. So far, none of these drugs has been studied in patients with airway disease.

**Vasoactive Intestinal Polypeptide Analogues**

Vasoactive intestinal polypeptide is a peptide that has 28 amino acids; it binds to two GPCRs, VPAC₁ and VPAC₂, both of which couple primarily to Gs to stimulate the adenylyl cyclase-cAMP-PKA pathway leading to relaxation of smooth muscle. VIP is a potent dilator of human airway smooth muscle in vitro but is not effective in patients because it is rapidly metabolized (plasma t₁/₂ ~ 2 min); in addition, VIP causes vasodilator side effects. More stable analogues of VIP, such as Ro 25-1533, which selectively stimulates VIP receptors in airway smooth muscle (via VPAC₁), have been synthesized. Inhaled Ro 25-1533 has a rapid bronchodilator effect in asthmatic patients, but it is not as prolonged as formoterol (Linden et al., 2003).

**Bitter Taste Receptor Agonists**

Bitter taste receptors (TAS2Rs) are GPCRs that are expressed in airway smooth muscle and mediate bronchodilation in response to agonists, such as quinine and chloroquine, even after β₂ receptor desensitization (An et al., 2012). However, these agonists are weak, so more potent drugs are needed.

**Other Inhibitors of Smooth Muscle Contraction**

Agents that inhibit the contractile machinery of airway smooth muscle, including rho kinase inhibitors, inhibitors of myosin light chain kinase, and myosin inhibitors, are also in development. Because these agents also cause vasodilation, it will be necessary to administer them by inhalation.

**Corticosteroids**

The introduction of ICSs, as a way of reducing the requirement and side effects of oral steroids, has revolutionized the treatment of chronic asthma (Barnes et al., 1998b). Because asthma is a chronic inflammatory disease, ICSs are considered first-line therapy in all but patients with the mildest disease. In marked contrast, ICSs are much less effective in COPD and should only be used in patients with severe disease who have frequent exacerbations. Oral corticosteroids remain the mainstay of treatment of several other pulmonary diseases, such as sarcoidosis, interstitial lung diseases, and pulmonary eosinophilic syndromes. The general pharmacology of corticosteroids is presented in Chapter 46.

**Mechanism of Action**

Corticosteroids enter target cells and bind to GRs in the cytoplasm (Chapter 46). There is only one type of GR that binds corticosteroids and no evidence for the existence of subtypes that might mediate different aspects of corticosteroid action (Barnes, 2011a). The steroid-GR complex moves into the nucleus, where it binds to specific sequences on the upstream regulatory elements of certain target genes, resulting in increased (or, rarely, decreased) transcription of the gene, with subsequent increased (or decreased) synthesis of the gene products.

The GRs may also interact with protein transcription factors and coactivator molecules in the nucleus and thereby influence the synthesis of certain proteins independently of any direct interaction with DNA. The repression of transcription factors, such as AP-1 and NF-κB, is likely to account for many of the anti-inflammatory effects of steroids in asthma. In particular, corticosteroids reverse the activating effect of these pro-inflammatory transcription factors on histone acetylation by recruiting HDAC2 to inflammatory genes that have been activated through acetylation of associated histones (Figure 40–7). GRs are acetylated when corticosteroids are bound and bind to DNA in this acetylated state as dimers, whereas the acetylated GR has to be deacetylated by HDAC2 to interact with inflammatory genes and NF-κB (Ito et al., 2006).

There may be additional mechanisms that are also important in the anti-inflammatory actions of corticosteroids. Corticosteroids have potent inhibitory effects on MAP kinase signaling pathways through the induction of MAP kinase phosphatase 1, which may inhibit the expression of multiple inflammatory genes (Clark, 2003).

![Figure 40–7] Mecha...
Anti-inflammatory Effects in Asthma

Corticosteroids have widespread effects on gene transcription, increasing the transcription of several anti-inflammatory genes and suppressing transcription of many inflammatory genes. Steroids have inhibitory effects on many inflammatory and structural cells that are activated in asthma and prevent the recruitment of inflammatory cells into the airways (Figure 40–8). In patients with mild asthma, the inflammation may be completely resolved after inhaled steroids.

Steroids potentiate the expression of multiple inflammatory cytokines, particularly cytokines released from Th2 cells. Corticosteroids also decrease eosinophil survival by inducing apoptosis. Corticosteroids inhibit the expression of multiple inflammatory genes in airway epithelial cells, probably the most important action of ICSs in suppressing asthmatic inflammation. Corticosteroids also prevent and reverse the increase in vascular permeability due to inflammatory mediators and may therefore lead to resolution of airway edema. Steroids have a direct inhibitory effect on mucus glycoprotein secretion from airway submucosal glands, as well as indirect inhibitory effects by downregulation of inflammatory stimuli that stimulate mucus secretion.

Corticosteroids have no direct effect on contractile responses of airway smooth muscle; improvement in lung function after ICSs is presumably due to an effect on the chronic airway inflammation, edema, and airway hyperresponsiveness. A single dose of an ICS has no effect on the early response to allergen (reflecting the ICSs lack of effect on mast cell mediator release) but inhibits the late response (which may be due to an effect on macrophages, eosinophils, and airway wall edema) and also inhibits the increase in airway hyperresponsiveness.

The ICSs have rapid anti-inflammatory effects, reducing airway hyperresponsiveness and inflammatory mediator concentrations in sputum within a few hours (Erin et al., 2008). However, it may take several weeks or months to achieve maximal effects on airway hyperresponsiveness, presumably reflecting the slow healing of the damaged inflamed airway. It is important to recognize that corticosteroids suppress inflammation in the airways but do not cure the underlying disease. When steroids are withdrawn, there is a recurrence of the same degree of airway hyperresponsiveness, although in patients with mild asthma it may take several months to return.

Effect on β2 Adrenergic Responsiveness

Steroids potentiate the effects of β2 agonists on bronchial smooth muscle and prevent and reverse β2 receptor desensitization in airways in vitro and in vivo (Barnes, 2002; Black et al., 2009). At a molecular level, corticosteroids increase the transcription of the β2 receptor gene in human lung in vitro and in the respiratory mucosa in vivo and also increase the stability of its messenger RNA. They also prevent or reverse uncoupling of β2 receptors to Gs. In animal systems, corticosteroids prevent downregulation of β2 receptors.

β2 Agonists also enhance the action of GRs, resulting in increased nuclear translocation of liganded GR receptors and enhancing the binding of GRs to DNA. This effect has been demonstrated in sputum macrophages of asthmatic patients after an ICS and inhaled LABA (Barnes, 2011a). This suggests that β2 agonists and corticosteroids enhance each other’s beneficial effects in asthma therapy.

Pharmacokinetics

The pharmacokinetics of oral corticosteroids are described in Chapter 46. The pharmacokinetics of ICSs are important in relation to systemic effects (Barnes et al., 1998b). The fraction of steroid that is inhaled into the lungs acts locally on the airway mucosa but may be absorbed from the airway and alveolar surface. Thus, a portion of an inhaled dose reaches the systemic circulation. Furthermore, the fraction of inhaled steroid that is deposited in the oropharynx is swallowed and absorbed from the gut. The absorbed fraction may be metabolized in the liver (first-pass metabolism) before reaching the systemic circulation (Figure 40–3). The use of a spacer chamber reduces oropharyngeal deposition and therefore reduces systemic absorption of ICSs, although this effect is minimal in corticosteroids with a high first-pass metabolism. Mouth rinsing and discarding the rinse have a similar effect, and this procedure should be used with high-dose dry powder steroid inhalers when spacer chambers cannot be used.

Beclomethasone dipropionate and ciclesonide are prodrugs that release the active corticosteroid after the ester group is cleaved by esterases in the lung. Ciclesonide is available as an MDI for asthma and as a nasal spray for allergic rhinitis. Budesonide and fluticasone propionate have a greater first-pass metabolism than BDP and are therefore less likely to produce systemic effects at high inhaled doses.

Routes of Administration and Dosing

Inhaled Corticosteroids in Asthma

Inhaled corticosteroids are recommended as first-line therapy for patients with persistent asthma. They should be started in any patient who needs to use a β2 agonist inhaler for symptom control more than twice weekly.
They are effective in mild, moderate, and severe asthma and in children as well as adults (Barnes et al., 1998b).

Most of the benefit may be obtained from doses of less than 400 μg BDP or equivalent. However, some patients (with relative corticosteroid resistance) may benefit from higher doses (up to 2000 μg/d). For most patients, ICSs should be used twice daily, a regimen that improves adherence once control of asthma has been achieved (which may require four-time daily dosing initially or a course of oral steroids if symptoms are severe). Administration once daily of some steroids (e.g., budesonide, mometasone, and ciclesonide in mild asthma and fluticasone furoate in all patients) is effective when doses of 400 μg or less are needed. If a dose greater than 800 μg daily via pMDI is used, a spacer device should be employed to reduce the risk of oropharyngeal side effects. ICSs may be used in children in the same way as in adults; at doses of 400 μg/d or less, there is no evidence of significant growth suppression (Pedersen, 2001). The dose of ICS should be the minimal dose that controls asthma; once control is achieved, the dose should be slowly reduced (Hawkins et al., 2003).

Nebulized corticosteroids (e.g., budesonide) are useful in the treatment of small children who are not able to use other inhaler devices.

**Inhaled Corticosteroids in COPD**

Patients with COPD occasionally respond to steroids, and these patients are likely to have concomitant asthma. Corticosteroids do not appear to have any significant anti-inflammatory effect in COPD; there appears to be an active resistance mechanism, which may be explained by impaired activity of HDAC2 as a result of oxidative stress (Barnes, 2013a). ICSs have no effect on the progression of COPD, even when given to patients with presymptomatic disease; in addition, ICSs have no effect on mortality (Yang et al., 2012). ICSs reduce the number of exacerbations in patients with severe COPD (FEV₁ < 50% predicted) who have frequent exacerbations and are recommended in these patients, although there is debate about whether these effects are due to inappropriate analysis of the data (Ernst et al., 2015).

Oral corticosteroids are used to treat acute exacerbations of COPD, but the effect is very small (Niewoehner et al., 1999). Patients with cystic fibrosis and bronchiectasis, which involve chronic neutrophilic inflammation of the airways, are also resistant to high doses of ICS.

**Systemic Steroids**

Intravenous steroids are indicated in acute asthma if lung function is less than 30% predicted and in patients who show no significant improvement with nebulized β₂ agonist. Hydrocortisone is the steroid of choice because it has the most rapid onset (5–6 h after administration), compared with 8 h with prednisolone. It is common to give hydrocortisone 4 mg/kg initially, followed by a maintenance dose of 3 mg/kg every 6 h. Methylprednisolone is also available for intravenous use. Intravenous therapy is usually given until a satisfactory response is obtained, and then oral prednisolone may be substituted. Oral prednisolone or prednisolone (40–60 mg) has a similar effect to intravenous hydrocortisone and is easier to administer. A high dose of inhaled fluticasone propionate (2000 μg daily) is as effective as a course of oral prednisolone in controlling acute exacerbations of asthma in a family practice setting and in children in an emergency department setting, although this route of delivery is more expensive (Manjra et al., 2000).

Prednisolone and prednisone are the most commonly used oral steroids. Maximal beneficial effect is usually achieved with 30–40 mg prednisone daily, although a few patients may need 60–80 mg daily to achieve control of symptoms. The usual maintenance dose is about 10–15 mg/d. Short courses of oral steroids (30–40 mg prednisolone daily for 1–2 weeks) are indicated for exacerbations of asthma; the dose may be tapered over 1 week after the exacerbation is resolved (the taper is not strictly necessary after a short course of therapy; but patients find it reassuring). Oral steroids are usually given as a single dose in the morning because this coincides with the normal diurnal increase in plasma cortisol and produces less adrenal suppression than if given in divided doses or at night.

**Adverse Effects**

Corticosteroids inhibit corticotropin and cortisol secretion by a negative-feedback effect on the pituitary gland (see Chapter 46).

Hypothalamic-pituitary-adrenal (HPA) axis suppression depends on dose and usually only occurs with doses of prednisone greater than 7.5–10 mg/d. Significant suppression after short courses of corticosteroid therapy is not usually a problem, but prolonged suppression may occur after several months or years. Steroid doses after prolonged oral therapy must be reduced slowly. Symptoms of “steroid withdrawal syndrome” include lassitude, musculoskeletal pains, and, occasionally, fever. HPA suppression with inhaled steroids is usually seen only when the daily inhaled dose exceeds 2000 μg BDP or its equivalent daily.

Side effects of long-term oral corticosteroid therapy include fluid retention, increased appetite, weight gain, osteoporosis, capillary fragility, hypertension, pectoral ulceration, diabetes, cataracts, and psychosis. Their frequency tends to increase with age. Very occasionally adverse reactions (such as anaphylaxis) to inhaled hydrocortisone have been described, particularly in aspirin-sensitive asthmatic patients.

The incidence of systemic side effects after ICSs is an important consideration, particularly in children (Lipworth, 1999) (Table 40–4). Initial studies suggested that adrenal suppression occurred only with inhaled doses greater than 1500–2000 μg/d. More sensitive measurements of systemic effects include indices of bone metabolism, such as serum osteocalcin and urinary pyridinium cross-links, and in children, knemometry, which may be increased with inhaled doses as low as 400 μg/d BDP in some patients. The clinical relevance of these measurements is not yet clear, however. Nevertheless, it is important to reduce the likelihood of systemic effects by using the lowest dose of inhaled steroid needed to control the asthma and by use of a large-volume spacer to reduce oropharyngeal deposition.

Several systemic effects of inhaled steroids have been described and include dermal thinning and skin capillary fragility (relatively common in elderly patients after high-dose inhaled steroids). Other side effects, such as cataract formation and osteoporosis, are reported but often in patients who are also receiving courses of oral steroids. There is some evidence that use of high-dose ICSs is associated with cataract and glaucoma, but it is difficult to dissociate the effects of ICS from the effects of courses of oral steroids that these patients usually require. There has been particular concern about the use of inhaled steroids in children because of growth suppression (Zhang et al., 2014).

The ICSs may have local side effects due to the deposition of inhaled steroid in the oropharynx. The most common problem is hoarseness and weakness of the voice (dysphonia) due to atrophy of the vocal cords following laryngeal deposition of steroid; it may occur in up to 40% of patients and is noticed particularly by patients who need to use their voices during their work (lecturers, teachers, and singers). Throat irritation and coughing after inhalation are common with MDIs and appear to be due to additives because these problems are not usually seen if the patient switches to a DPI. There is no evidence for atrophy of the lining of the airway. Oropharyngeal candidiasis occurs in about 5% of patients. There is no evidence for increased lung infections, including tuberculosis, in patients with asthma.

that reduces corticosteroid responsiveness; this is potentially reversible inflammatory actions of corticosteroids. In those with COPD and some patients with severe asthma, in asthmatic patients who smoke, and in (which mediates much of the anti-inflammatory effect). Such “dissociation effects) from the inhibitory effect on transcription factors such as NF-κB able. It has been possible to develop corticosteroids that dissociate the (Derendorf, 2007). Fluticasone furoate has the longest duration of action and is suitable for once-daily dosing (Woodcock et al., 2011).

Growing evidence suggests that high doses of ICSs increase the risk of pneumonia in patients with COPD (Finney et al., 2014); the risk appears to be higher with fluticasone propionate than budesonide. Corticosteroid MDIs with HFA propellants produce smaller aerosol particles and may have a more peripheral deposition, making them useful in treating patients with more severe asthma.

Therapeutic Choices

Numerous ICSs are now available, including BDP, triamcinolone, flunisolide, budesonide, beclomethasone, mometasone, fluticasone furoate, ciclesonide, and fluticasone furoate. All are equally effective as antiasthma drugs, but there are differences in their pharmacokinetics: Budesonide, fluticasone, mometasone, and ciclesonide have a lower oral bioavailability than BDP because they are subject to greater first-pass hepatic metabolism; this results in reduced systemic absorption from the fraction of the inhaled drug that is swallowed (Derendorf et al., 2006) and thus reduced adverse effects. At high doses (>1000 μg), budesonide and fluticasone propionate have fewer systemic effects than BDP and triamcinolone (not marketed in the U.S.), and they are preferred in patients who need high doses of ICSs and in children. Ciclesonide is another choice; it is a prodrug that is converted to the active metabolite by esterases in the lung, giving it low oral bioavailability and a high therapeutic index (Derendorf, 2007). Fluticasone furoate has the longest duration of action and is suitable for once-daily dosing (Woodcock et al., 2011).

When doses of inhaled steroid exceed 800 μg BDP or equivalent daily, a large-volume spacer is recommended to reduce oropharyngeal deposition and systemic absorption in the case of BDP. All currently available ICSs are absorbed from the lung into the systemic circulation, so that some systemic absorption is inevitable. However, the amount of drug absorbed does not appear to have clinical effects in doses of less than 800 μg BDP equivalent. Although there are potency differences among corticosteroids, there are relatively few comparative studies, partly because dose comparison of corticosteroids is difficult due to their long time course of action and the relative flatness of their dose-response curves.

Future Developments

Early treatment with ICSs in both adults and children may give a greater improvement in lung function than if treatment is delayed (Buse et al., 2008), likely reflecting the fact that corticosteroids are able to modify the underlying inflammatory process and prevent structural changes (fibrosis, smooth muscle hyperplasia, etc.). ICSs are currently recommended for patients with persistent asthmatic symptoms (e.g., need for an inhaled β2 agonist more than twice a week).

Developing new corticosteroids with fewer systemic effects is desirable. It has been possible to develop corticosteroids that dissociate the DNA-binding effect of corticosteroids (which mediates most of the adverse effects) from the inhibitory effect on transcription factors such as NF-κB (which mediates much of the anti-inflammatory effect). Such “dissociated steroids” or selective GR agonists should, theoretically, retain anti-inflammatory activity but have a reduced risk of adverse effects; achieving this separation of desired and adverse effects is difficult in vivo (Belvisi et al., 2001). Nonsteroidal selective GR agonists are now in development.

Corticosteroid resistance is a major barrier to effective therapy in patients with severe asthma, in asthmatic patients who smoke, and in patients with COPD and cystic fibrosis (Barnes, 2013a; Barnes and Adcock, 2009). “Steroid-resistant” asthma is thought to be due to reduced anti-inflammatory actions of corticosteroids. In those with COPD and some patients with severe asthma, there is a reduction in HDAC2 expression that reduces corticosteroid responsiveness; this is potentially reversible by existing treatments, such as low-dose theophylline and nortriptyline.

Cromones

Cromolyn sodium (sodium cromoglicate) is a derivative of khellin, an Egyptian herbal remedy, and was found to protect against allergen challenge without any bronchodilator effect. A structurally related drug, nedocromil sodium, which has a similar pharmacological profile to cromolyn, was subsequently developed. Although cromolyn was popular in the past because of its good safety profile, its use has sharply declined with the more widespread use of the more effective ICSs, particularly in children.

Phosphodiesterase Inhibitors

The PDE inhibitors relax smooth muscle and inhibit inflammatory cells through an increase in cellular cAMP. PDE4 is the predominant PDE isoenzyme in inflammatory cells, including mast cells, eosinophils, neutrophils, T lymphocytes, macrophages, and structural cells such as sensory nerves and epithelial cells (Hatzelmann et al., 2010), suggesting that PDE4 inhibitors could be useful as an anti-inflammatory treatment in both asthma and COPD.

In animal models of asthma, PDE4 inhibitors reduce eosinophil infiltration and responses to allergen, whereas in COPD they are effective against smoke-induced inflammation and emphysema. In COPD, an oral PDE4 inhibitor, roflumilast, has been approved for patients with COPD with severe disease (FEV1 < 50% predicted, frequent exacerbations, and chronic bronchitis). Given once daily by mouth, it reduces exacerbations but has little effect on symptoms and lung function (Calverley et al., 2009), although it is effective on top of long-acting bronchodilators and ICSs (Martinez et al., 2015). The relatively weak efficacy is due to dose limitations as a result of side effects, particularly diarrhea, headaches, and nausea.

Of the four subfamilies of PDE4, PDE4D is the major form whose inhibition is associated with vomiting: inhibition of PDE4B is important for anti-inflammatory effects. Thus, selective PDE4B inhibitors may have a greater therapeutic index. Inhaled PDE4 inhibitors, to reduce systemic absorption and adverse responses, have proved to be ineffective. A dual PDE3/4 inhibitor gives bronchodilation in patients with COPD when given by nebulization, but it is uncertain whether there are significant anti-inflammatory effects (Franciosi et al., 2013).

Mediator Antagonists

Both H1 antihistamines and anti-LTs have been applied to airway disease, but their added benefit over β2 agonists and corticosteroids is slight (Barnes, 2004; Barnes et al., 1998a).

Antihistamines

Histamine mimics many of the features of asthma and is released from mast cells in acute asthmatic responses, suggesting that antihistamines may be useful in asthma therapy. There is little evidence that histamine H1 receptor antagonists provide any useful clinical benefit, as demonstrated by a meta-analysis (van Ganse et al., 1997). Newer antihistamines, including cetirizine and azelastine, have some beneficial effects, but this may be unrelated to H1 receptor antagonism. Antihistamines are not recommended in the routine management of asthma.

Antileukotrienes

There is considerable evidence that cyst-LTs are produced in asthma and that they have potent effects on airway function, inducing bronchoconstriction, airway hyperresponsiveness, plasma exudation, mucus secretion, and eosinophil inflammation (Figure 40–9; also see Chapter 37). These findings led to the development of 5′-lipoxygenase (5-LO) enzyme inhibitors (of which zileuton is the only drug marketed) and several antagonists of the cys-LT1 receptor, including montelukast (s, saфrelukast, and pranlukast (not available in the U.S.).

Clinical Studies

In patients with mild-to-moderate asthma, anti-LTs cause a significant improvement in lung function and asthma symptoms, with a reduction in the use of rescue inhaled β2 agonists. Several studies showed evidence for a bronchodilator effect, with an improvement in baseline lung function, suggesting that LTs are contributing to the baseline bronchoconstriction...
in asthma, although this varies among patients. However, anti-LTs are considerably less effective than ICSs in the treatment of mild asthma and cannot be considered the treatment of first choice (Chauhan and Ducharme, 2012). Anti-LTs are indicated as an add-on therapy in patients who are not well controlled on ICSs. The added benefit is small, equivalent to doubling the dose of ICS, and less effective than adding a LABA. Anti-LTs have a beneficial effect in allergic rhinitis and have a similar efficacy to antihistamines (Grayson and Koenenblat, 2007).

In patients with severe asthma who are not controlled on high doses of ICS and LABA, anti-LTs do not appear to provide any additional benefit (Robinson et al., 2001). Theoretically, anti-LTs should be of particular value in patients with aspirin-sensitive asthma because they block the airway response to aspirin challenge; however, their benefit is no greater here than in other types of asthma.

Anti-LTs are effective in preventing exercise-induced asthma, with efficacy similar to that of LABAs (Coreno et al., 2000). Anti-LTs appear to act mainly as anticholinergic drugs, and they are clearly less broadly effective than β2 agonists because they antagonize only one of several anticholinergic mediators.

The cys-LT1 receptor antagonists have no role in the therapy of COPD. LTs, a potent neutrophil chemoattractant, is elevated in COPD, indicating that 5-LO inhibitors that inhibit LT synthesis may have some potential benefit by reducing neutrophil inflammation. However, a pilot study failed to indicate any clear benefit of a 5-LO inhibitor in patients with COPD (Bernstein et al., 2011).

**Adverse Effects**

Zileuton, zafirlukast, and montelukast are all associated with rare cases of hepatic dysfunction; thus, liver-associated enzymes should be monitored. Several cases of Churg-Strauss syndrome have been associated with the use of zafirlukast and montelukast. Churg-Strauss syndrome is a rare vasculitis that may affect the heart, peripheral nerves, and kidney and is associated with increased circulating eosinophils and asthma. Cases of Churg-Strauss syndrome have been described in patients on anti-LTs who were not on concomitant corticosteroid therapy, suggesting there is a causal link (Nathani et al., 2008).

**Future Developments**

One of the major advantages of anti-LTs is their effectiveness in tablet form. This may increase compliance with chronic therapy and makes treatment of children easier. Montelukast is effective as a once-daily preparation (10 mg in adults, 5 mg in children). In addition, oral administration may treat concomitant allergic rhinitis. However, the clinical studies indicated a modest effect on lung function and symptom control. This is not surprising. There are many mediators besides cys-LTs involved in the pathophysiology of asthma, and anti-LTs are unlikely to be as effective as a β2 agonist, which will counteract bronchoconstriction regardless of the spasmogen. It is likely that anti-LTs will be used less in the future because combination inhalers are the mainstay of asthma therapy.

Some patients appear to show better responses than others, suggesting that LTs may play a more important role in some patients. The variability in response to anti-LTs may reflect differences in production of or responses to LTs in different patients, and this in turn may be related to polymorphisms of 5-LO, LTC4, synthase, or cys-LT, receptors that are involved in the synthesis of LTs (Tantisira and Drazen, 2009).

**Immunomodulatory Therapies**

**Immunosuppressive Therapy**

Immunosuppressive therapy (e.g., methotrexate, cyclosporine A, gold, intravenous immunoglobulin) has been considered in asthma when other treatments have been unsuccessful or to reduce the dose of oral steroids required. However, immunosuppressive treatments are less effective and have a greater propensity for side effects than oral corticosteroids and therefore cannot be routinely recommended.

**Anti-IgE Receptor Therapy**

Increased specific IgE is a fundamental feature of allergic asthma. *Omalizumab* is a humanized monoclonal antibody that blocks the binding of IgE to high-affinity IgE receptors (FcεRI) on mast cells and thus prevents their activation by allergens (Figure 40–10). It also blocks binding on IgE to low-affinity IgE receptors (FcεRII, CD23) on other inflammatory cells, including γδT and B lymphocytes, macrophages, and possibly eosinophils, to inhibit chronic inflammation. *Omalizumab* also reduces levels of circulating IgE.

**Future Developments**

One of the major advantages of anti-LTs is their effectiveness in tablet form. This may increase compliance with chronic therapy and makes treatment of children easier. Montelukast is effective as a once-daily preparation (10 mg in adults, 5 mg in children). In addition, oral administration may treat concomitant allergic rhinitis. However, the clinical studies indicated a modest effect on lung function and symptom control. This is not surprising. There are many mediators besides cys-LTs involved in the pathophysiology of asthma, and anti-LTs are unlikely to be as effective as a β2 agonist, which will counteract bronchoconstriction regardless of the spasmogen. It is likely that anti-LTs will be used less in the future because combination inhalers are the mainstay of asthma therapy.

Some patients appear to show better responses than others, suggesting that LTs may play a more important role in some patients. The variability in response to anti-LTs may reflect differences in production of or responses to LTs in different patients, and this in turn may be related to polymorphisms of 5-LO, LTC4, synthase, or cys-LT, receptors that are involved in the synthesis of LTs (Tantisira and Drazen, 2009).

**Immunosuppressive Therapy**

Immunosuppressive therapy (e.g., methotrexate, cyclosporine A, gold, intravenous immunoglobulin) has been considered in asthma when other treatments have been unsuccessful or to reduce the dose of oral steroids required. However, immunosuppressive treatments are less effective and have a greater propensity for side effects than oral corticosteroids and therefore cannot be routinely recommended.

**Anti-IgE Receptor Therapy**

Increased specific IgE is a fundamental feature of allergic asthma. *Omalizumab* is a humanized monoclonal antibody that blocks the binding of IgE to high-affinity IgE receptors (FcεRI) on mast cells and thus prevents their activation by allergens (Figure 40–10). It also blocks binding on IgE to low-affinity IgE receptors (FcεRII, CD23) on other inflammatory cells, including γδT and B lymphocytes, macrophages, and possibly eosinophils, to inhibit chronic inflammation. *Omalizumab* also reduces levels of circulating IgE.

**Future Developments**

One of the major advantages of anti-LTs is their effectiveness in tablet form. This may increase compliance with chronic therapy and makes treatment of children easier. Montelukast is effective as a once-daily preparation (10 mg in adults, 5 mg in children). In addition, oral administration may treat concomitant allergic rhinitis. However, the clinical studies indicated a modest effect on lung function and symptom control. This is not surprising. There are many mediators besides cys-LTs involved in the pathophysiology of asthma, and anti-LTs are unlikely to be as effective as a β2 agonist, which will counteract bronchoconstriction regardless of the spasmogen. It is likely that anti-LTs will be used less in the future because combination inhalers are the mainstay of asthma therapy.

Some patients appear to show better responses than others, suggesting that LTs may play a more important role in some patients. The variability in response to anti-LTs may reflect differences in production of or responses to LTs in different patients, and this in turn may be related to polymorphisms of 5-LO, LTC4, synthase, or cys-LT, receptors that are involved in the synthesis of LTs (Tantisira and Drazen, 2009).
Clinical Use
Omalizumab is used for the treatment of patients with severe asthma (Humbert et al., 2014). The antibody is administered by subcutaneous injection every 2–4 weeks, and the dose is determined by the titer of circulating total IgE. Omalizumab reduces the requirement for oral and ICSs and markedly reduces asthma exacerbations. Not all patients respond, and there are no clear clinical predictors of clinical response, necessitating a trial of therapy (usually over 4 months). Because of its high cost, this treatment is generally used only in patients with very severe asthma who are poorly controlled even on oral corticosteroids and in patients with very severe concomitant allergic rhinitis (Normannen et al., 2014). It may also be of value in protecting against anaphylaxis during specific immunotherapy. A recent study suggested that omalizumab may be effective in preventing asthma exacerbations if administered prior to the exacerbation season (Teach et al., 2015); this is linked to increased expression of type I interferons, which boost antiviral immunity. The major side effect of omalizumab is an anaphylactic response, which is uncommon (<0.1%).

Specific Immunotherapy
Although specific immunotherapy is effective in allergic rhinitis due to single allergens, there is little evidence that desensitizing injections to common allergens are effective in controlling chronic asthma (Rolland et al., 2009). Specific immunotherapy induces the secretion of the anti-inflammatory cytokine IL-10 from regulatory helper T lymphocytes, and this blocks costimulatory signal transduction in T cells (via CD28) so that they are unable to react to allergens presented by antigen-presenting cells (Ozdemir et al., 2016). Applying an understanding of the cellular processes involved might lead to safer and more effective approaches in the future. More specific immunotherapies may be developed with cloned allergen epitopes, T-cell peptide fragments of allergens, CpG oligonucleotides, and vaccines of conjugates of allergen and toll-like receptor 9 to activate T lymphocytes, and may have therapeutic potential. Several cytokine or cytokine receptor–blocking antibodies are in clinical development for asthma (Chung, 2015), but there has been less progress in COPD.

Blocking IL-4, which determines IgE synthesis and eosinophilic inflammation, has been ineffective in clinical studies. However, blocking IL-13 or its shared receptor with IL-4 (IL-4Ra) provides some clinical benefit and reduces exacerbations but is not yet approved (Hanania et al., 2015; Wenzel et al., 2013).

Production of TNF-α is increased in asthma and COPD and may play a key role in amplifying airway inflammation, through the activation of NF-κB, AP-1, and other transcription factors. However, in patients with COPD and in patients with severe asthma, anti–TNF-α blocking antibodies have been ineffective, at the expense of increasing infections and malignancies (Rennard et al., 2007; Wenzel et al., 2009).

Chemokine Receptor Antagonists
Many chemokines are involved in asthma and COPD and play a key role in recruitment of inflammatory cells, such as eosinophils, neutrophils, macrophages, and lymphocytes, into the lungs. Chemokine receptors are attractive targets because they areGPCRs; small-molecule inhibitors are now in development (Donnelly and Barnes, 2006). In asthma, CCR3 antagonists, which should block eosinophil recruitment into the airways, are the most favored target, but several small-molecule CCR3 antagonists have failed in development because of toxicity. In COPD, CXCR2 antagonists, which prevent neutrophil and monocyte chemotaxis due to CXC chemokines, such as CXCL1 and CXCL8, have been effective in animal models of COPD and in neutrophilic inflammation in normal subjects, but in clinical trials in patients with COPD, an oral CXCR2 antagonist provided little clinical benefit (Rennard et al., 2015).

Protease Inhibitors
Several proteolytic enzymes are involved in the chronic inflammation of airway diseases. Mast cell tryptase has several effects on airways, including increasing responsiveness of airway smooth muscle to constrictors, increasing plasma exudation, potentiating eosinophil recruitment, and stimulating fibroblast proliferation. Some of these effects are mediated by activation of protease-activated receptor, PAR2. Tryptase inhibitors have so far proved to be disappointing in clinical studies.

Proteases are involved in the degradation of connective tissue in COPD, particularly enzymes that break down elastin fibers, such as neutral elastase and MMPs, which are involved in emphysema. Neutrophil elastase inhibitors have been difficult to develop, and there are no positive clinical studies in patients with COPD. MMP9 appears to be the predominant elastolytic enzyme in emphysema, and several selective inhibitors are now in development.

New Drugs in Development for Airway Disease
Several new classes of drug are in development for asthma and COPD, but clinical development has been slow, and many treatments have either proved to be ineffective or are limited by toxicity and side-effect profiles (Barnes, 2012, 2013b).

Novel Mediator Antagonists
Blocking the receptors or synthesis of inflammatory mediators is a logical approach to the development of new treatments for asthma and COPD. However, in both diseases many different mediators are involved, and therefore blocking a single mediator is unlikely to be effective unless it plays a unique and key role in the disease process. Several specific mediator antagonists have been found to be ineffective in asthma, including antagonists/inhibitors of thromboxane, platelet-activating factor, bradykinin, and tachykinins. However, these blockers have often been not tested in COPD, in which different mediators are involved. A number of other approaches are under study, as noted next.

CORT2 Antagonists
The chemotactic factor for T2 cells has been identified as prostanoid DP2 receptor (Chapter 37). Several DP2/CORT2 antagonists are now in development for asthma, with some promising initial results in patients with eosinophilic inflammation (Townley and Agrawal, 2012).

Antioxidants
Oxidative stress is important in severe asthma and COPD and may contribute to corticosteroid resistance. Existing antioxidants include vitamins C and E and N-acetyl-cysteine. These drugs have weak effects, but more potent antioxidants are in development, including activators of the transcription factor Nrf2 (Kirkham and Barnes, 2013).
This has prompted a search for specific blockers of these transcription factors. NF-κB is naturally inhibited by IkB, which is degraded after activation by specific kinases. Small-molecule inhibitors of the IkB kinase IKK2 (or IKKβ) are in clinical development (Ziegelbauer et al., 2005). These drugs may be of particular value in COPD, for which corticosteroids are largely ineffective. However, there are concerns that inhibition of NF-κB may cause side effects such as increased susceptibility to infections, which has been observed in gene disruption studies when components of NF-κB are inhibited.

Mitogen-Activated Protein Kinase Inhibitors

The MAP kinase pathways are involved in chronic inflammation. There has been particular interest in the p38 MAP kinase pathway that is blocked by a novel class of drugs, such as losmapimod (Norman, 2015). These drugs inhibit the synthesis of many inflammatory cytokines, chemokines, and inflammatory enzymes. The p38 MAP kinase inhibitors are in development for the treatment of asthma (they inhibit TLR2 cytokine synthesis) and for COPD (they inhibit neutrophilic inflammation and signaling of inflammatory cytokines and chemokines). However, clinical studies have given disappointing results in patients with COPD, and the dose is limited by side effects (MacNee et al., 2013). Several inhaled p38 inhibitors are in development to reduce the risk of side effects (Millan, 2011).

Mucoregulators

Mucus hypersecretion occurs in chronic bronchitis, COPD, cystic fibrosis, and asthma (Fahy and Dickeys, 2010). In chronic bronchitis, mucus hypersecretion is related to chronic irritation by cigarette smoke and may involve neural mechanisms and the activation of neutrophils to release enzymes such as neutrophil elastase and proteinase 3 that have powerful stimulatory effects on mucus secretion. Mast cell-derived chymase is also a potent mucus secretagogue. This suggests that several classes of drugs may be developed to control mucus hypersecretion. Mucus secretion is regulated by epidermal growth factor receptors, which lead to increased mucin gene expression, but a nebulized epidermal growth factor receptor inhibitor has been ineffective in COPD (Woodruff et al., 2010).

Systemic anticholinergic drugs appear to reduce mucociliary clearance, but this is not observed with either ipratropium bromide or tiotropium bromide, presumably reflecting their poor absorption from the respiratory tract. β2 Agonists increase mucus production and mucociliary clearance and have been shown to increase ciliary beat frequency in vitro. Because inflammation leads to mucus hypersecretion, anti-inflammatory treatments should reduce mucus hypersecretion, anti-inflammatory treatments should reduce mucus hypersecretion; ICSs are very effective in reducing increased mucus production in asthma.

Mucolytics

Several agents can reduce the viscosity of sputum in vitro. One group consists of derivatives of cysteine that reduce the disulfide bridges that bind glycoproteins to other proteins, such as albumin and secretory IgA. These drugs also act as antioxidants and may therefore reduce airway inflammation. Only N-acetylcysteine is available in the U.S.; carboxypeptidase, methyldopa, testosterone, and bromhexine are available elsewhere. Orally administered, these agents are relatively well tolerated, but clinical studies in chronic bronchitis, asthma, and bronchiectasis have been disappointing. A large controlled study of oral N-acetylcysteine in patients with COPD showed no effect in disease progression or in preventing exacerbations, although there was some benefit in the patients not treated with ICSs (Decramer et al., 2005), as confirmed in a subsequent studies of carboxypeptidase and N-acetylcysteine in patients with COPD not treated with other medications (Zheng et al., 2008, 2014). N-Acetylcysteine is not currently recommended for COPD management.

DNase (dornase alfa) reduces mucus viscosity in sputum of patients with cystic fibrosis and is indicated if there is significant symptomatic and lung function improvement after a trial of therapy (Henke and Ratjen, 2007). There is no evidence that dornase alfa is effective in COPD or asthma, however.

Expectorants

Expectorants are oral drugs that are supposed to enhance the clearance of mucus. Although expectorants were once commonly prescribed, there is little or no objective evidence for their efficacy. Such drugs are often emetic that are given in subemetic doses on the basis that gastric irritation may stimulate an increase in mucus clearance via a reflex mechanism. Lacking evidence for their efficacy, the FDA has removed most expectorants from the market in a review of over-the-counter drugs. With the exception of guaifenesin, no agents are approved as expectorants in the U.S. In patients who find it difficult to clear mucus, adequate hydration and inhalation of steam may be of some benefit.

Antitussives

Despite the fact that cough is a common symptom of airway disease, its mechanisms are poorly understood, and current treatment is unsatisfactory (Pavord and Chung, 2008). Viral infections of the upper respiratory tract are the most common cause of cough; postviral cough is usually self-limiting and commonly patient medicated. Their wide use notwithstanding, over-the-counter cough medications are largely ineffective (Dicpinigaitis et al., 2014). Because cough is a defensive reflex, its suppression may be inappropriate in bacterial lung infection. Before treatment with antitussives, it is important to identify underlying causal mechanisms that may require therapy.

Whenever possible, treat the underlying cause, not the cough. Asthma commonly presents as cough, and the cough will usually respond to ICSs. A syndrome characterized by cough in association with sputum eosinophilia but no airway hyperresponsiveness, termed eosinophilic bronchitis, also responds to ICSs (Birring et al., 2003). Nonasthmatic cough does not respond to ICSs but sometimes responds to anticholinergic therapy. The cough associated with postnasal drip of sinusitis responds to antibiotics (if warranted), nasal decongestants, and intranasal steroids. The cough associated with ACE inhibitors (in ~ 15% of patients treated) responds to lowering the dose or withdrawal of the drug and substitution of an AT1 receptor antagonist (see Chapter 26). Gastroesophageal reflux is a common cause of cough through a reflex mechanism and occasionally as a result of acid aspiration into the lungs. This cough may respond to suppression of gastric acid with an H2 receptor antagonist or a proton pump inhibitor (see Chapter 49). Some patients have a chronic cough with no obvious cause, and this chronic idiopathic cough or cough hypersensitivity syndrome may be due to airway sensory neural hyperesthesia (Haque et al., 2005). There are several treatments that have been assessed in the treatment of refractory cough (Gibson et al., 2016).

Opiates

Opiates have a central mechanism of action on MORs in the medullary cough center, but there is some evidence that they may have additional peripheral action on cough receptors in the proximal airways. Codeine and pholcodine (not available in the U.S.) are commonly used, but there is little evidence that they are clinically effective, particularly on postviral cough; in addition, they are associated with sedation and constipation. Morphine and methadone are effective but indicated only for intractable cough associated with bronchial carcinoma.

Dextromethorphan

Dextromethorphan is a centrally active NMDA receptor antagonist. It may also antagonize opioid receptors. Despite the fact that it is in numerous over-the-counter cough suppressants and used commonly to treat cough, it is poorly effective. In children with acute nocturnal cough, it is often ineffective. and up to 600 mg/d, if needed. Although clinical studies shortly after its approval showed some efficacy, benzotenate (200 mg) was not effective in suppressing experimentally induced cough (Dicpinigaitis et al., 2009). Side effects include dizziness and dysphagia. Seizures and cardiac arrest have occurred following an acute ingestion. Severe allergic reactions have been reported in patients allergic to \textit{para-aminobenzoic acid}, a metabolite of benzotenate.

\textbf{Neuromodulators}

\textit{Gabapentin} and pregabalin are GABA analogues that inhibit neurotransmission and have been used in neuropathic pain syndromes. They have been shown to benefit chronic idiopathic cough, which also involved neural hypersensitivity (Gibson and Vertigan, 2015). Side effects of somnolence and dizziness are common at higher doses, so it is usual to initiate therapy at lower doses.

\textbf{Other Drugs}

Several other drugs reportedly have small benefits in protecting against cough challenges or in reducing cough in pulmonary diseases. These drugs include \textit{moguisteine} (not available in the U.S.), which acts peripherally and appears to open ATP-sensitive K+ channels. \textit{Theobromine}, a naturally occurring methylxanthine, reduces cough induced by tussive agents. Although the expectorant \textit{guaifenesin} is not typically known as a cough suppressant, it is significantly better than placebo in reducing acute viral cough and inhibits cough-reflex sensitivity in patients with upper respiratory tract infections (Dicpinigaitis et al., 2009).

\textbf{Novel Antittussives}

There is clearly a need to develop new, more effective therapies for cough, particularly drugs that act peripherally to avoid sedation. There are close analogies between chronic cough and sensory hyperesthesia, so new therapies with novel antittussives are likely to arise from pain research.

\textbf{Transient Receptor Potential Antagonists}

Several types of TRP ion channels have been described on airway sensory nerves and may be activated by various mediators and physical factors, resulting in cough. TRPV1 (previously called the \textit{vanilloid receptor}) is activated by capsaicin, \textit{H+}, and bradykinin, all of which are potent tussive agents. \textbf{TRPV1 inhibitors} block cough induced by capsaicin and bradykinin and are effective in some models of cough (McLeod et al., 2008). In a clinical study of an oral TRPV1 inhibitor, there was protection against capsaicin-induced cough but no clinical improvement in chronic idiopathic cough after long-term treatment (Khalid et al., 2014). A side effect of these drugs is loss of temperature regulation and hyperthermia, which has prevented clinical development.

\textbf{ATP Receptor Antagonists}

Adenosine triphosphate is a potent tussive agent and stimulates cough in patients with asthma and COPD via activation of P2X3 receptors on afferent nerves (Basoglu et al., 2015). A \textbf{P2X3 antagonist} (AF-219) is effective in reducing chronic idiopathic cough, although abnormal taste (dysgeusia) is a frequent side effect (Abdulqawi et al., 2015).

\textbf{Drugs for Dyspnea and Ventilatory Control}

\textbf{Drugs for Dyspnea}

Bronchodilators should reduce breathlessness in patients with airway obstruction. Chronic oxygen use may have a beneficial effect, but in a few patients dyspnea may be extreme. Drugs that reduce breathlessness may also depress ventilation in parallel and may therefore be dangerous in severe asthma and COPD. Some patients show a beneficial response to dihydrocodeine and diazepam; however, these drugs must be used with great caution because of the risk of ventilatory depression (Currow et al., 2014). Slow-release morphine tablets may also be helpful in patients with COPD with extreme dyspnea (Currow and Abernethy, 2007). Nebulized morphine may also reduce breathlessness in COPD and could act in part on opioid receptors in the lung. Nebulized furosemide has some efficacy in treating dyspnea from a variety of causes, but the evidence is not yet sufficiently convincing to recommend this as routine therapy (Newton et al., 2008).

\textbf{Ventilatory Stimulants}

Selective respiratory stimulants are indicated if ventilation is impaired as a result of overdose with sedatives, in postanesthetic respiratory depression, and in idiopathic hypventilation. Respiratory stimulants are rarely indicated in COPD because respiratory drive is already maximal, and further stimulation of ventilation may be counterproductive because of the increase in energy expenditure caused by the drugs.

\textbf{Doxapram}

At low doses (0.5 mg/kg IV), doxapram stimulates carotid chemoreceptors; at higher doses, it stimulates medullary respiratory centers. Its effect is transient; thus, intravenous infusion (0.3–3 mg/kg per min) is needed for sustained effect. Unwanted effects include nausea, sweating, anxiety, and hallucinations. At higher doses, increased pulmonary and systemic pressures may occur. Both the kidney and the liver participate in the clearance of doxapram, which should be used with caution if hepatic or renal function is impaired. In COPD, the infusion of doxapram is restricted to 2 h. The use of doxapram to treat ventilatory failure in COPD has now largely been replaced by noninvasive ventilation.

\textbf{Almitrine}

Almitrine bimesylate is a pipеразине derivative that appears to selectively stimulate peripheral chemoreceptors and is without central actions. Almitrine stimulates ventilation only when there is hypoxia. Long-term use of almitrine is associated with peripheral neuropathy, limiting its availability in most countries, including the U.S.

\textbf{Acetazolamide}

The carbonic anhydrase inhibitor acetazolamide (see Chapter 25) induces metabolic acidosis and thereby stimulates ventilation, but it is not widely used because the metabolic imbalance it produces may be detrimental in the face of respiratory acidosis. It has a small beneficial effect in respiratory failure in patients with COPD. The drug has proved useful in prevention of high-altitude (mountain) sickness (Faisi et al., 2016).

\textbf{Naloxone}

Naloxone is a competitive opioid antagonist that is indicated only if ventilatory depression is due to overdose of opioids.

\textbf{Flumazenil}

Flumazenil is a benzodiazepine receptor antagonist that can reverse respiratory depression due to overdose of benzodiazepines (Veiraiah et al., 2012).

Hematopoiesis

The finite life span of most mature blood cells requires their continuous replacement, a process termed hematopoiesis. New cell production must respond to basal needs and states of increased demand. Erythrocyte production can increase more than 20-fold in response to anemia or hypoxemia, leukocyte production increases dramatically in response to systemic infections, and platelet production can increase 10- to 20-fold when platelet consumption results in thrombocytopenia.

The regulation of blood cell production is complex. Hematopoietic stem cells are rare marrow cells that manifest self-renewal and lineage commitment, resulting in cells destined to differentiate into the 10 or more distinct blood cell lineages. For the most part, this process occurs in the marrow cavities of the skull, vertebral bodies, pelvis, and proximal long bones; it involves interactions among hematopoietic stem and progenitor cells and the cells and complex macromolecules of the marrow stroma and is influenced by a number of soluble and membrane-bound hematopoietic growth factors. Several hormones and cytokines have been identified and cloned that affect hematopoiesis, permitting their production in quantities sufficient for research and, in some cases, therapeutic use. Clinical applications range from the treatment of primary hematologic diseases (e.g., aplastic anemia, congenital neutropenia) to use as adjuncts with kidney failure or those undergoing cancer chemotherapy or marrow transplantation.

Hematopoiesis also requires an adequate supply of minerals (e.g., iron, cobalt, and copper) and vitamins (e.g., folic acid, vitamin B₁₂, pyridoxine, ascorbic acid, and riboflavin); deficiencies generally result in characteristic anemias or, less frequently, a general failure of hematopoiesis (Hoffbrand and Herbert, 1999). Therapeutic correction of a specific deficiency state depends on the accurate diagnosis of the anemic state and on knowledge about the correct dose, the use of these agents in appropriate combinations, and the expected response.

Growth Factor Physiology

Steady-state hematopoiesis encompasses the tightly regulated production of more than 400 billion blood cells each day. The hematopoietic organ also is unique in adult physiology in that several mature cell types are derived from a much smaller number of multipotent progenitors, which develop from a more limited number of pluripotent hematopoietic stem cells. Such cells are capable of maintaining their own number and differentiating under the influence of cellular and humoral factors to produce the large and diverse number of mature blood cells.

Our understanding of stem cell differentiation owes much to the in vitro culture of marrow cells. Using the results from clonal cultures in semisolid medium, stem cell differentiation can be described as a series of developmental steps that produce mixed blood cell lineage colonies, which give rise to large, immature and small, mature single-lineage burst-forming units (BFUs) and colony-forming units (CFUs), respectively, for each of the major blood cell types. These early progenitors (BFUs and CFUs) are capable of further proliferation and differentiation, increasing their number by some 30-fold. It is at this most mature stage of development that the lineage-committed growth factors (G-CSF, M-CSF, erythropoietin, and thrombopoietin) exert their primary proliferative and differentiative effects. Overall, proliferation and maturation of the CFU for each cell line can amplify the resulting mature cell product by another 30-fold or more, generating more than 1000 mature cells from each committed stem cell.

Hematopoietic and lymphopoietic growth factors are glycoproteins produced by a number of marrow cells and peripheral tissues. They are active at very low concentrations and typically affect more than one committed cell lineage. Most interact synergistically with other factors and stimulate production of additional growth factors, a process termed networking. Growth factors generally exert actions at several points in the processes of cell proliferation and differentiation and in mature cell function. However, the network of growth factors that contributes to any given cell lineage depends absolutely on a nonredundant, lineage-specific

**Erythropoiesis-Stimulating Agents**

_Erythropoiesis-stimulating agent_ (ESA) is the term given to a pharmacological substance that stimulates red blood cell production.

**Erythropoietin**

Erythropoietin is the most important regulator of the proliferation of committed erythroid progenitors (CFU-E) and their immediate progeny. In its absence, severe anemia is invariably present, commonly seen in patients with renal failure. Erythropoiesis is controlled by a feedback system in which a sensor in the kidney detects changes in oxygen delivery to modulate the erythropoietin secretion. The sensor mechanism is now understood at the molecular level (Haase, 2010).

_Hypoxia-inducible factor_ (HIF) is a heterodimeric (HIF-1α and HIF-1β) transscription factor, enhances expression of multiple hypoxia-inducible genes, such as vascular endothelial growth factor and erythropoietin. HIF-1α is labile due to its prolyl hydroxylation and subsequent polyubiquitination and degradation, aided by the von Hippel-Lindau (VHL) protein. During states of hypoxia, the prolyl hydroxylase is inactive, allowing the accumulation of HIF-1α and activating erythropoietin expression, which in turn stimulates rapid expansion of erythroid progenitors. Specific alteration of VHL leads to an oxygen-sensing defect, characterized by constitutively elevated levels of HIF-1α and erythropoietin, with resultant polycythemia (Gordeuk et al., 2004). A second isoform of HIF, HIF-2α, is an important factor, such that absence of factors that stimulate developmentally early progenitors is compensated for by redundant cytokines, but loss of the lineage-specific factor leads to a specific cytopenia.

Some of the overlapping and nonredundant effects of the more important hematopoietic growth factors are illustrated in Figure 41–1 and Table 41–1.
regulator of the expression of genes that contribute to iron absorption (Mastrogiannaki et al., 2013); a genetic gain-of-function mutation in HFE-2a also induces erythrocytosis in patients (Percy et al., 2008).

Erythropoietin is expressed primarily in peritubular interstitial cells of the kidney. Erythropoietin contains 193 amino acids, of which the first 27 are cleaved during secretion. The final hormone is heavily glycosylated and has a molecular mass of about 30 kDa. After secretion, erythropoietin binds to a receptor on the surface of committed erythroid progenitors in the marrow and is internalized. With anemia or hypoxemia, synthesis rapidly increases by 100-fold or more, serum erythropoietin levels rise, and marrow progenitor cell survival, proliferation, and maturation are dramatically stimulated. This finely tuned feedback loop can be disrupted by kidney disease, marrow damage, or a deficiency in iron or an essential vitamin. With an infection or an inflammatory state, erythropoietin secretion, iron delivery, and progenitor proliferation all are suppressed by inflammatory cytokines, but this accounts for only part of the resultant anemia; interference with iron metabolism also is an effect of inflammatory mediator effects on the hepatic protein hepcidin (Drakesmith and Prentice, 2012). Loss of hepcidin-producing liver mass or genetic or acquired conditions that repress hepcidin production by the liver may lead to iron overload (Pietrangelo, 2016).

Preparations
Preparations of recombinant human erythropoietin include epoetin alfa, epoetin beta, epoetin omega, and epoetin zeta, which differ almost exclusively in carbohydrate modifications due to manufacturing differences and are supplied in single-use vials or syringes containing 500–40,000 units for intravenous or subcutaneous administration. When injected intravenously, epoetin alfas are cleared from plasma with a t<sub>1/2</sub> of 4–8 h. However, the effect on marrow progenitors lasts much longer, and once-weekly dosing can be sufficient to achieve an adequate response. An engineered epoetin alfa, darbepoetin, which displays a longer circulatory half-life, is also available for use in patients with indications similar to those for other epoetins. Based on phage display technology, small peptide agonists of the erythropoietin receptor were identified and developed into clinical agents by coupling to polyethylene glycol. One such erythropoiesis-stimulating peptide, peginesatide, was approved for the treatment of anemia due to chronic kidney disease; postmarketing reports of serious hypersensitivity reactions and anaphylaxis necessitated its removal from the market.

Recombinant human erythropoietin (epoetin alfa) is nearly identical to the endogenous hormone. The carbohydrate modification pattern of epoetin alfa differs slightly from the native protein, but this difference apparently does not alter kinetics, potency, or immunoreactivity of the drug. Modern assays can detect these differences and thereby identify athletes who use the recombinant product for “blood doping.”

Therapeutic Uses, Monitoring, and Adverse Effects
Recombinant erythropoietin therapy, in conjunction with adequate iron intake, can be highly effective in a number of anemias, especially those associated with poor erythropoietic response. Epoetin alfa is effective in the treatment of anemias associated with surgery, AIDS, cancer chemotherapy, prematurity, and certain chronic inflammatory conditions. Darbepoetin alfa also has been approved for use in patients with anemia associated with chronic kidney disease. A Cochrane analysis could not demonstrate the superiority of one form of ESA over any another.

During erythropoietin therapy, absolute or functional iron deficiency may develop. Functional iron deficiency (i.e., normal ferritin levels but low transferrin saturation) presumably results from the inability to mobilize iron stores rapidly enough to support the increased erythropoiesis. Supplemental iron therapy is recommended for all patients whose serum ferritin is less than 100 μg/L or whose serum transferrin saturation is below 20%. During initial therapy and after any dosage adjustment, the

Hematopoietic agents: growth factors, minerals, and vitamins

Hematopoietic growth factors

Hematopoietic growth factors stimulate cell proliferation and differentiation. These factors are divided into four main categories: erythropoietin (EPO), stem cell factor (SCF), interleukins, and colony-stimulating factors. Erythropoietin stimulates the production of red blood cells and is especially important in the treatment of anemia. Stem cell factor enhances hematopoiesis and is essential for the development of hematopoietic cells. Interleukins play a crucial role in immune responses and inflammation. Colony-stimulating factors, such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), stimulate the growth and differentiation of myeloid cells. Thrombopoietin (TPO) is critical for megakaryocyte development and platelet production.

**HEMATOPOIETIC GROWTH FACTORS**

**Erythropoietin (EPO)**
- Stimulates proliferation and maturation of committed erythroid progenitors to increase red cell production

**Stem cell factor (SCF, c-kit ligand, Steel factor) and FLT 3 ligand (FL)**
- Act synergistically with a wide range of other colony-stimulating factors and interleukins to stimulate pluripotent and committed stem cells
- FL also stimulates both dendritic and NK cells (antitumor response)
- SCF also stimulates mast cells and melanocytes

**Interleukins**
- IL-1, IL-3, IL-5, IL-6, IL-9, and IL-11
- IL-1, IL-2, IL-4, IL-7, and IL-12
- IL-6
- IL-6 stimulates human myeloma cells to proliferate
- IL-6 and IL-11 stimulate BFU-Meg to increase platelet production
- IL-1, IL-2, IL-4, IL-7, and IL-12
- IL-8 and IL-10
- Numerous immunological activities involving B- and T-cell functions
- IL-8 acts as a chemotactic factor for basophils and neutrophils

**Granulocyte-macrophage colony-stimulating factor (G-CSF)**
- Acts synergistically with SCF, IL-1, IL-3, and IL-6 to stimulate CFU-GM and CFU-Meg to increase neutrophil and monocyte production
- With EPO may promote BFU-E formation
- Enhances migration, phagocytosis, superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils
- Prevents alveolar proteinosis

**Granulocyte colony-stimulating factor (G-CSF)**
- Stimulates BFU-G to increase neutrophil production

**Monocyte/macrophage colony-stimulating factor (M-CSF, CSF-1)**
- Stimulates CFU-M to increase monocyte precursors
- Activates and enhances function of monocyte/macrophages

**Macrophage colony-stimulating factor (M-CSF)**
- Stimulates CFU-M to increase monocyte/macrophage precursors
- Acts in concert with tissues and other growth factors to determine the proliferation, differentiation, and survival of a range of cells of the mononuclear phagocyte system

**Thrombopoietin (TPO, Mpl ligand)**
- Stimulates the self-renewal and expansion of hematopoietic stem cells
- Stimulates stem cell differentiation into megakaryocyte progenitors
- Selectively stimulates megakaryopoiesis to increase platelet production
- Acts synergistically with other growth factors, especially IL-6 and IL-11

Hematopoietic growth factors play a crucial role in the production of blood cells and are essential for the treatment of various conditions, including anemia and hematological malignancies.
the HAART era, such that the origin of anemia in HIV-infected individuals today is different from what it was at the onset of the AIDS epidemic.

**Cancer-Related Anemias**

Epoetin alfa therapy, 150 units/kg three times a week or 450–600 units/kg once a week, can reduce the transfusion requirement in patients with cancer undergoing chemotherapy as well as lead to reduced anemia-related symptoms. Previous therapeutic guidelines (Rizzo et al., 2002) recommended the use of epoetin alfa in patients with chemotherapy-associated anemia when hemoglobin levels fall below 10 g/dL, basing the decision to treat less-severe anemia (hemoglobin 10–12 g/dL) on clinical circumstances. For anemia associated with hematologic malignancies, the guidelines support the use of recombinant erythropoietin in patients with low-grade myelodysplastic syndrome. In this setting, neutropenia often dictates the use of G-CSF, which frequently augments the erythroid response to erythropoietin. In responding patients, the response duration is usually 2–3 years. A baseline serum erythropoietin level may help to predict the response; most patients with blood levels greater than 500 IU/L are unlikely to respond to any dose of the drug. Most patients treated with epoetin alfa experience an improvement in their anemia and their sense of well-being (Littlewood et al., 2001). Following these recommendations, case reports suggested a direct effect of both epoetin alfa and darbepoetin alfa in stimulation of tumor cells. A meta-analysis of a large number of patients and clinical trials estimated the risk at about 10% higher than for cancer patients not treated (Bohlius et al., 2009). Following on these results, new guidelines were issued (Rizzo et al., 2010). This finding is continuing to be evaluated by the FDA and warrants serious attention.

**Use in Perioperative Patients**

Epoetin alfa has been used perioperatively to treat anemia (hematocrit 30%–36%) and reduce the need for allogeneic erythrocyte transfusion in nonanemic patients during and following surgery in patients with moderate or large anticipated blood loss. Patients undergoing elective orthopedic and cardiac procedures have been treated with 150–300 units/kg of epoetin alfa once daily for the 10 days preceding surgery, on the day of surgery, and for 4 days after surgery. As an alternative, 600 units/kg can be given on days 21, 14, and 7 before surgery, with an additional dose on the day of surgery. Using these dosing regimens, an average of four units of autologous blood can be obtained for postoperative use in a typical, nonanemic patient.

**Other Uses**

Epoetin alfa has received orphan drug status from the FDA for the treatment of the anemia of prematurity, HIV infection, and myelodysplasia. In the last case, even very high doses (>1000 units/kg two to three times a week) sometimes have limited success. Highly competitive athletes have used epoetin alfa to increase their hemoglobin levels (“blood doping”) and improve performance. Unfortunately, this misuse of the drug has been implicated in the deaths of several athletes and is strongly discouraged.

---

**Myeloid Growth Factors**

The myeloid growth factors are glycoproteins that stimulate the proliferation and differentiation of one or more myeloid cell types. Recombinant forms of several growth factors have been produced, including GM-CSF, G-CSF, IL-3, M-CSF or CSF-1, and stem cell factor (SCF) (see Table 41–1), although only G-CSF and GM-CSF have found meaningful clinical applications.

Myeloid growth factors are produced naturally by a number of different cells, including fibroblasts, endothelial cells, macrophages, and T cells (Figure 41–2). These factors are active at extremely low concentrations and act via membrane receptors of the cytokine receptor superfamily to activate the Jak/STAT signal transduction pathway. GM-CSF can stimulate proliferation, differentiation, and function of a number of the myeloid cell lineages (see Figure 41–1). It acts synergistically with other growth factors, including erythropoietin, at the level of the BFU. GM-CSF stimulates CFU-GM, CFU-M, CFU-E, and CFU-Meg to increase cell production. GM-CSF also enhances the migration, phagocytosis, superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils (Weisbart et al., 1987).

---

**Granulocyte-Macrophage Colony-Stimulating Factor**

Recombinant human GM-CSF (sargramostim) is a glycoprotein with 127 amino acids. The primary therapeutic effect of sargramostim is to stimulate myelopoiesis.

The initial clinical application of sargramostim was in patients undergoing autologous marrow transplantation. By shortening the duration of neutropenia, transplant morbidity was significantly reduced without a change in long-term survival or risk of inducing an early relapse of the malignant process (Brandt et al., 1988).

The role of GM-CSF therapy in allogeneic transplantation is less clear. Its effect on neutrophil recovery is less pronounced in patients receiving prophylactic treatment of graft-versus-host disease (GVHD). However, it may improve survival in transplant patients who exhibit early graft failure (Nemunaitis et al., 1990).

It also has been used to mobilize CD34-positive progenitor cells for peripheral blood stem cell (PBSC) collection for transplantation after myeloablative chemotherapy (Haas et al., 1990). Sargramostim has been used to shorten the period of neutropenia and reduce morbidity in patients receiving intensive cancer chemotherapy (Gerhartz et al., 1993).

Sargramostim is administered by subcutaneous injection or slow intravenous infusion at doses of 125–500 μg/m2/d. Plasma levels of GM-CSF rise rapidly after subcutaneous injection and then decline with a t1/2 of 2–3 h. When given intravenously, infusions should be maintained over 3–6 h. With the initiation of therapy, there is a transient decrease in the absolute leukocyte count secondary to cell margination and pulmonary vascular sequestration. This is followed by a dose-dependent, biphasic increase in leukocyte counts over the next 7–10 days. Once the drug is discontinued, the leukocyte count returns to baseline within 2–10 days. When GM-CSF is given in lower doses, the response is primarily neutrophilic, whereas monocytosis and eosinophilia are observed at larger doses. After hematopoietic stem cell transplantation or intensive chemotherapy, sargramostim...
HEMATOPOIETIC AGENTS: GROWTH FACTORS, MINERALS, AND VITAMINS

Development of future malignancy. Previous studies have shown an increase in patients on long-term therapy. Mild-to-moderate splenomegaly has been observed in those with sickle cell anemia, as it has been known to precipitate severe crises. In 2004 and 2006, two papers were published on the use of filgrastim and ligepristim.

Filgrastim is effective in the treatment of severe neutropenia after autologous hematopoietic stem cell transplantation and high-dose cancer chemotherapy (Lieschke and Burgess, 1992). Like GM-CSF, filgrastim shortens the period of severe neutropenia and reduces morbidity secondary to bacterial and fungal infections (Hammoud et al., 1989). G-CSF also is effective in the treatment of severe congenital neutropenias. Filgrastim therapy can improve neutrophil counts in some patients with myelodysplasia or marrow damage (moderately SAA or tumor infiltration of the marrow). The neutropenia of patients with AIDS receiving zidovudine also can be partially or completely reversed.

Filgrastim is routinely used in patients undergoing PBSC collection for stem cell transplantation. It promotes the release of CD34+ progenitor cells from the marrow, reducing the number of collections necessary for transplant. G-CSF–induced mobilization of stem cells into the circulation also has the potential to enhance repair of other damaged organs in which PBSCs might play a role. PBSC grafts have a higher cell dose and somewhat more committed progenitor cells than steady-state marrow grafts, resulting in faster engraftment and faster immunological reconstitution.

Filgrastim is administered by subcutaneous injection or intravenous infusion over at least 30 min at doses of 1–20 μg/kg/d. The usual starting dose in a patient receiving myelosuppressive chemotherapy is 5 μg/kg/d. The distribution and clearance rate from plasma (t½ of 3.5 h) are similar for both routes of administration. The recommended dose for pegfilgrastim is fixed at 6 mg for patients weighing more than 20 kg, administered either subcutaneously once per chemotherapy cycle. As with GM-CSF therapy, G-CSF administered after hematopoietic stem cell transplantation or intensive cancer chemotherapy will increase granulocyte production and shorten the period of severe neutropenia. Frequent blood cell counts should be obtained to determine the effectiveness of the treatment and guide dosage adjustment. In patients who received intensive myelosuppressive cancer chemotherapy, daily administration of G-CSF for 14–21 days or more may be necessary to correct the neutropenia.

Adverse Reactions

Adverse reactions to filgrastim include mild-to-moderate bone pain in patients receiving high doses over a protracted period, local skin reactions following subcutaneous injection, and rare cutaneous necrotizing vasculitis. Patients with a history of hypersensitivity to proteins produced by Escherichia coli should not receive the drug; the same holds for patients with sickle cell anemia, as it has been known to precipitate severe crises and even death. Mild-to-moderate splenomegaly has been observed in patients on long-term therapy.

Patients with sickle cell anemia should not be administered G-CSF as it is reported to trigger severe crises. In 2004 and 2006, two papers were published suggesting that previously healthy stem cell donors receiving human G-CSF for mobilization displayed marrow cell changes concerning for the development of future malignancy. Previous studies have shown an increase in myeloid leukemia in patients with breast cancer receiving G-CSF for neutropenia. However, careful follow-up has failed to reveal any meaningful increase in myeloid leukemia in normal stem cell donors administered G-CSF.

Thrombopoietic Growth Factors

Interleukin 11

Interleukin 11 is a cytokine that stimulates hematopoiesis, intestinal epithelial cell growth, and osteoclastogenesis and inhibits adipogenesis. IL-11 also enhances megakaryocyte maturation in vitro. Recombinant human IL-11, orelvekin, t½ about 7 h, leads to a thrombopoietic response in 5–9 days when administered daily to normal subjects.

The drug is administered to patients at 25–50 μg/kg per day subcutaneously. Orelvekin is approved for use in patients undergoing chemotherapy for nonmyeloid malignancies with severe thrombocytopenia (platelet count < 20 × 10⁹/L), and it is administered until the platelet count returns to more than 100 × 10⁹/L. The major complications of therapy are fluid retention and associated cardiac symptoms, such as tachycardia, palpitation, edema, and shortness of breath; this is a significant concern in elderly patients and often requires concomitant therapy with diuretics. Also reported are blurred vision, injection site rash or erythema, and phlebitis.

Thrombopoietin Receptor Agonists

Thrombopoietin

Thrombopoietin, a glycoprotein produced by the liver, marrow stromal cells, and other organs, is the primary regulator of platelet production. Two forms of recombinant thrombopoietin have been tested for clinical use. One is a truncated version of the native protein, termed recombinant human megakaryocyte growth and development factor (rHuMGDF) that is covalently modified with polyethylene glycol to increase the circulatory t½. The second is the full-length polypeptide termed recombinant human thrombopoietin (rHuTPO).

While use in thrombocytopenic clinical trial subjects was found to be safe, the use of rHuMGDF in a clinical trial of normal platelet donors, designed to boost the quantity of donated platelets, led to donor thrombocytopenia in several subjects due to the immunogenicity of this agent (Li et al., 2001). This experience led to both agents being abandoned for clinical use and to the development of small-molecular mimics of recombinant thrombopoietin, termed TRAs. Two of these agents are FDA approved for use in patients with immune thrombocytopenia (ITP), and one of the TRAs is also approved for use in patients with severe aplastic anemia (SAA) who have failed to respond to more conventional treatments. Romiplostim contains four copies of a small peptide that binds with high affinity to the thrombopoietin receptor, grafted onto an immunoglobulin scaffold. Romiplostim is safe and efficacious in patients with ITP (Kuter et al., 2008). The drug is administered weekly by subcutaneous injection, starting with a dose of 1 μg/kg, titrated to a maximum of 10 μg/kg, until the platelet count increases above 50 × 10⁹/L. Eltrombopag is a small organic TRA that is administered orally; the recommended starting dose is 50 mg/d, titrated to 75 mg depending on platelet response. These and additional TRAs are undergoing clinical trials, in ITP and SAA, as well as in chemotherapy-induced thrombocytopenia and in several marrow disorders, including myelodysplastic syndromes.

Iron Deficiency and Other Hypochromic Anemias

The Bioavailability of Iron

Iron exists in the environment largely as ferric oxide, ferric hydroxide, and polymers. In this state, its biological availability is limited unless solubilized by acid or chelating agents. For example, bacteria and some plants produce high-affinity chelating agents that extract iron from the surrounding environment. Most mammals have little difficulty in acquiring iron; this is explained by ample iron intake and perhaps also by a greater efficiency in absorbing iron. Humans, however, appear to be an exception. Although total dietary intake of elemental iron in humans usually exceeds requirements, the bioavailability of the iron in the diet is limited.
Iron deficiency is the most common nutritional cause of anemia in humans. It can result from inadequate iron intake, malabsorption, blood loss, or an increased requirement, as with pregnancy. When severe, it results in a characteristic microcytic, hypochromic anemia. In addition to its role in metabolism of iron, transferrin saturation, plasma ferritin, and red cell protoporphyrin permitted the definition and detection of the body’s iron store status and iron-deficient erythropoiesis. In 1994, Feder and colleagues identified the HFE gene, which is mutated in type 1 hemochromatosis (Feder et al., 1996). Subsequently, Ganz and colleagues discovered a peptide produced by the liver, which was termed hepcidin (Park et al., 2001), now known to be the master regulator of iron homeostasis and to play a role in anemia of chronic disease (Ganz and Nemeth, 2011).

**Metabolism of Iron**

The body store of iron is divided between essential iron—containing compounds and excess iron, which is held in storage (Table 41–2). Hemoglobin dominates the essential fraction. Each hemoglobin molecule contains four atoms of iron, amounting to 1.1 mg (20 μmol) of iron/mL of red blood cells. Other forms of essential iron include myoglobin and a variety of heme and nonheme iron-dependent enzymes. Ferritin is a protein-iron storage complex that exists as individual molecules or as aggregates. Apoferritin (MW – 450 kDa) is composed of 24 polypeptide subunits that form an outer shell around a storage cavity for polynuclear hydrous ferric oxide phosphate. More than 30% of the weight of ferritin may be iron (400 atoms of iron per ferritin molecule). Ferritin aggregates, referred to as hemosiderin and visible by light microscopy, constitute about one-third of normal stores. The two predominant sites of iron storage are the reticuloendothelial system and the hepatocytes.

Internal exchange of iron is accomplished by the plasma protein transferrin, a 76-kDa glycoprotein that has two binding sites for ferric iron. Iron is delivered from transferrin to intracellular sites by means of specific transferrin receptors in the plasma membrane. The iron-transferrin complex binds to the receptor, and the ternary complex is internalized through clathrin-coated pits by receptor-mediated endocytosis. A proton-pumping ATPase lowers the pH of the intracellular vesicular compartment (the endosomes) to about 5.5. Iron subsequently dissociates, and the receptor returns the apotransferrin to the cell surface, where it is released into the extracellular environment. Cells regulate their expression of transferrin receptors and intracellular ferritin in response to the iron supply (De Domenico et al., 2008). The synthesis of apoferritin and transferrin receptors is regulated posttranscriptionally by two iron-regulating proteins, IRP1 and IRP2. These IRPs are cytosolic RNA-binding proteins that bind to iron-regulating elements (IREs) present in the 5′ or 3′ untranslated regions of mRNA encoding apoferritin or the transferrin receptors, respectively. Binding of these IREs to the 5′ IRE of apoferritin mRNA represses translation, whereas binding to the 3′ IRE of mRNA encoding the transferrin receptors enhances transcript stability, thereby increasing protein production.

The flow of iron through the plasma amounts to a total of 30–40 mg/d in the adult (~0.46 mg/kg of body weight). The major internal circulation of iron involves the erythron and reticuloendothelial cells (Figure 41–3). About 80% of the iron in plasma goes to the erythroid marrow to be packaged into new erythrocytes; these normally circulate for about 120 days before being catabolized by the reticuloendothelial system. At that time, a portion of the iron is immediately returned to the plasma bound to transferrin, while another portion is incorporated into the ferritin stores of reticuloendothelial cells and returned to the circulation more gradually. With abnormalities in erythocyte maturation, the predominant portion of iron assimilated by the erythroid marrow may be rapidly localized in the reticuloendothelial cells as defective red cell precursors are broken down; this is termed ineffective erythropoiesis. The rate of iron turnover in plasma may be reduced by half or more with red cell aplasia, with all the iron directed to the hepatocytes for storage.

The human body conserves its iron stores to a remarkable degree. Only 10% of the total is lost per year by normal men (i.e., ~1 mg/d). Two-thirds of this iron is excreted from the GI tract as extravasated red cells, iron in bile, and iron in exfoliated mucosal cells. The other third is accounted for by small amounts of iron in desquamated skin and in the urine. Additional losses of iron occur in women due to menstruation. Although the average loss in menstruating women is about 0.5 mg per day, 10% of menstruating
HEMATOPOIETIC AGENTS: GROWTH FACTORS, MINERALS, AND VITAMINS

A ferrireductase, duodenal cytochrome B, located on the luminal surface is presented to the intestinal mucosa as either inorganic iron or heme iron. 2009). After acidification and partial digestion of food in the stomach, iron is absorbed independent of the diet composition; it therefore represents 30% of iron absorbed (Conrad and Umbreit, 2000). The nonheme fraction represents the larger amount of dietary iron ingested by the economically underprivileged. In a vegetarian diet, nonheme iron is absorbed poorly because of the inhibitory action of a variety of dietary components, particularly phosphates. Ascorbic acid and meat facilitate the absorption of nonheme iron. In developed countries, the normal adult diet contains about 6 mg of iron per 1000 calories, providing an average daily intake for adult men of between 12 and 20 mg and for adult women of between 8 and 15 mg. Foods high in iron (>5 mg/100 g) include organ meats such as liver and heart, brewer’s yeast, wheat germ, egg yolks, oysters, and cereals.

Genetic polymorphism and consequent dysfunction in hepcidin or in proteins regulating its expression can result in inadequate levels of hepcidin and cause hereditary hemochromatosis (Pietrangelo, 2016). This can be due to polymorphism in HFE, resulting in a Cys→Tyr change at position 282 (C282Y) in the HFE protein, or pathogenic mutations in hepcidin (HAMP), ferroportin (FPN), hemojuvelin (HJV), or transferrin receptor 2 (TfR2). The phenotype may vary, ranging from severe, as in HJV− or HAMP−juvenile-onset hemochromatosis, to relatively milder forms of adult-onset hemochromatosis, resulting from defects in FPN or TfR2. Acquired hemochromatosis can result from excessive amounts of parenteral iron, such as may occur in multiple transfusions for hereditary anemia or acquired aplastic anemia, from loss of hepcidin-producing liver mass, or with disease factors such as hepatitis C or chronic alcoholism that impair the production of hepcidin.

### Iron Requirements: Availability of Dietary Iron

Adult men must absorb only 13 μg of iron/kg of body weight/d (–1 mg/d), whereas menstruating women require about 21 μg/kg (–1.4 mg) per day. In the last two trimesters of pregnancy, requirements increase to about 80 μg/kg (5–6 mg) per day; infants have similar requirements due to their rapid growth (Table 41–4).

The difference between dietary supply and requirements is reflected in the size of iron stores, which are low or absent when iron balance is precarious and high when iron balance is favorable. In infants after the third month of life and in pregnant women after the first trimester, stores of iron are negligible. Menstruating women have approximately one-third the stored iron found in adult men (see Table 41–2).

Although the iron content of the diet obviously is important, of greater nutritional significance is the bioavailability of iron in food. Heme iron, which constitutes only 6% of dietary iron, is far more available and is absorbed independent of the diet composition; it therefore represents 30% of iron absorbed (Conrad and Umbreit, 2000). The nonheme fraction represents the larger amount of dietary iron ingested by the economically underprivileged. In a vegetarian diet, nonheme iron is absorbed poorly because of the inhibitory action of a variety of dietary components, particularly phosphates. Ascorbic acid and meat facilitate the absorption of nonheme iron. In developed countries, the normal adult diet contains about 6 mg of iron per 1000 calories, providing an average daily intake for adult men of between 12 and 20 mg and for adult women of between 8 and 15 mg. Foods high in iron (>5 mg/100 g) include organ meats such as liver and heart, brewer’s yeast, wheat germ, egg yolks, oysters, and certain dried beans and fruits; foods low in iron (<1 mg/100 g) include milk and milk products and most nongreen vegetables. Iron also may be added from cooking in iron pots. In assessing dietary iron intake, it is important to consider not only the amount of iron ingested but also its bioavailability.

### Iron Deficiency

The prevalence of iron deficiency anemia in the U.S. is in the order of 1%–4% and depends on the economic status of the population (McLean et al., 2009). In developing countries, up to 20%–40% of infants and pregnant women may be affected. Better iron balance has resulted from the practice of fortifying flour, the use of iron-fortified formulas

for infants, and the prescription of medicinal iron supplements during pregnancy.

Iron deficiency anemia results from dietary intake of iron that is inadequate to meet normal requirements (nutritional iron deficiency), blood loss, or interference with iron absorption (Camaschella, 2015). More severe iron deficiency is usually the result of blood loss, either from the GI tract or, in women, from the uterus. Finally, treatment of patients with erythropoietin can result in a functional iron deficiency. Iron deficiency in infants and young children can lead to behavioral disturbances and can impair development, which may not be fully reversible. Iron deficiency in children also can lead to an increased risk of lead toxicity secondary to pica and an increased absorption of heavy metals. Premature and low-birthweight infants are at greatest risk for developing iron deficiency, especially if they are not breast fed or do not receive iron-fortified formula (Finch, 2015). After the age of 2–3 years, the requirement for iron declines until adolescence, when rapid growth combined with irregular dietary habits again increase the risk of iron deficiency. Adolescent girls are at greatest risk; the dietary iron intake of most girls ages 11–18 is insufficient to meet their requirements.

Treatment of Iron Deficiency

General Therapeutic Principles

The response of iron deficiency anemia to iron therapy is influenced by several factors, including the severity of anemia, the ability of the patient to tolerate and absorb medicinal iron, and the presence of other complicating illnesses. Therapeutic effectiveness is best measured by the resulting increase in the rate of production of red cells. The magnitude of the marrow response to iron therapy is proportional to the severity of the anemia (level of erythropoietin stimulation) and the amount of iron delivered to marrow precursors.

The patient’s ability to tolerate and absorb medicinal iron is a key factor in determining the rate of response to therapy. The small intestine regulates absorption and, with increasing doses of oral iron, limits the entry of iron into the bloodstream. This provides a natural ceiling on how much iron can be supplied by oral therapy. In the patient with moderately severe iron deficiency anemia, tolerable doses of oral iron will deliver, at most, 40–60 mg of iron per day to the erythroid marrow. This is an amount sufficient for production rates of two to three times normal.

Clinically, the effectiveness of iron therapy is best evaluated by tracking the reticulocyte response and the rise in the hemoglobin or the hematocrit. An increase in the reticulocyte count is not observed for at least 4–7 days after beginning therapy. A measurable increase in the hemoglobin level takes even longer. A decision regarding the effectiveness of treatment should not be made for 3–4 weeks after the start of treatment. An increase of 20 g/L or more in the concentration of hemoglobin by that time should be considered a positive response, assuming that no other change in the patient’s clinical status can account for the improvement and that the patient has not been transfused.

If the response to oral iron is inadequate, the diagnosis must be reconsidered. A full laboratory evaluation should be conducted, and poor compliance by the patient or the presence of a concurrent inflammatory disease must be explored. A source of continued bleeding obviously should be sought. If no other explanation can be found, an evaluation of the patient’s ability to absorb oral iron should be considered. There is no justification for merely continuing oral iron therapy beyond 3–4 weeks if a favorable response has not occurred.

Once a response to oral iron is demonstrated, therapy should be continued until the hemoglobin returns to normal. Treatment may be extended if it is desirable to replenish iron stores. This may require a considerable period of time because the rate of absorption of iron by the intestine will decrease markedly as iron stores are reconstituted. The prophylactic use of oral iron should be reserved for patients at high risk, including pregnant women, women with excessive menstrual blood loss, and infants. Iron supplements also may be of value for rapidly growing infants who are consuming substandard diets and for adults with a recognized cause of chronic blood loss. Except for infants, in whom the use of supplemented formulas is routine, the use of over-the-counter mixtures of vitamins and minerals to prevent iron deficiency should be discouraged.

Therapy With Oral Iron

Orally administered ferrous sulfate is the treatment of choice for iron deficiency. Ferrous salts are absorbed about three times as well as ferric salts. Variations in the particular ferrous salt have relatively little effect on bioavailability; the sulfate, fumarate, succinate, gluconate, aspartate, other ferrous salts, and polysaccharide-ferric hydrate complex are absorbed to approximately the same extent. The effective dose of all of these preparations is based on iron content.

Other iron compounds have utility in fortification of foods. Reduced iron (metallic iron, elemental iron) is as effective as ferrous sulfate, provided that the material employed has a small particle size. Large-particle ferrum reductum and iron phosphate salts have much lower bioavailability. Ferric edetate has been shown to have good bioavailability and to have advantages for maintenance of the normal appearance and taste of food. The amount of iron in iron tablets is important. It also is essential that the coating of the tablet dissolve rapidly in the stomach. Delayed-release preparations are available, but absorption from such preparations varies. Ascorbic acid (≥200 mg) increases the absorption of medicinal iron by at least 30%. However, the increased uptake is associated with an increase in the incidence of side effects. Preparations that contain other compounds with therapeutic action, such as vitamin B12, folate, or cobalt, are not recommended because the patient’s response to the combination cannot easily be interpreted.

The average dose for the treatment of iron deficiency anemia is about 200 mg of iron per day (2–3 mg/kg), given in three equal doses of 65 mg. Children weighing 15–30 kg can take half the average adult dose; small children and infants can tolerate relatively large doses of iron (e.g., 5 mg/kg). When the object is the prevention of iron deficiency in pregnant women, for example, doses of 15 to 30 mg of iron per day are adequate. Bioavailability of iron is reduced with food and by concurrent antacids. For a rapid response or to counteract continued bleeding, as much as 120 mg of iron may be administered four times a day.

The duration of treatment is governed by the rate of recovery of hemoglobin (Table 41–5) and the desire to create iron stores. The former depends on the severity of the anemia. With a daily rate of repair of 2 g of hemoglobin per liter of whole blood, the red cell mass usually is reconstituted within 1–2 months. Thus, an individual with a hemoglobin of 50 g per liter can achieve a normal complement of 150 g/L in about 50 days, whereas an individual with a hemoglobin of 100 g/L may take only half that time. The creation of stores of iron requires many months of oral iron administration. The rate of absorption decreases rapidly after recovery from anemia, and after 3–4 months of treatment, stores may increase at a rate of not much more than 100 mg/month. Much of the strategy of continued therapy depends on the estimated future iron balance. Patients with an inadequate diet may require continued therapy with low doses of iron. If the bleeding has stopped, no further therapy is required after the hemoglobin has returned to normal. With continued bleeding, long-term, high-dose therapy clearly is indicated.

Untoward Effects of Oral Preparations of Iron. Side effects of oral iron preparations include heartburn, nausea, upper gastric discomfort, and diarrhea or constipation. A good policy is to initiate

</table>
therapy at a small dosage and then gradually to increase the dosage to that desired. Only individuals with underlying disorders that augment the absorption of iron run the hazard of developing iron overload (hemochromatosis).

**Iron Poisoning.** Large amounts of ferrous salts are toxic, but fatalities are rare in adults. Most deaths occur in children, particularly between the ages of 12 and 24 months. As little as 1–2 g of iron may cause death, but 2–10 g usually is ingested in fatal cases. All iron preparations should be kept in childproof bottles. Signs and symptoms of severe poisoning may occur within 30 min after ingestion or may be delayed for several hours. They include abdominal pain, diarrhea, or vomiting of brown or bloody stomach contents containing pills. Of particular concern are pallor or cyanosis, lassitude, drowsiness, hyperventilation due to acidosis, and cardiovascular collapse. If death does not occur within 6 h, there may be a transient period of apparent recovery, followed by death in 12–24 h. The corrosive injury to the stomach may result in pyloric stenosis or gastric scarring.

In the evaluation of a child thought to have ingested iron, a color test for iron in the gastric contents and determination of the concentration of iron in plasma can be performed. If the latter is less than 63 μmol (3.5 mg/L), the child is not in immediate danger. However, vomiting should be induced when there is iron in the stomach, and an X-ray should be taken to evaluate the number of pills remaining in the small bowel (iron tablets are radiopaque). When the plasma concentration of iron is greater than the total iron-binding capacity (63 μmol; 3.5 mg/L), deferoxamine should be administered (see Chapter 71). The speed of diagnosis and therapy is important. With early treatment, the mortality from iron poisoning can be reduced from 45% to about 1%. Deferiprone and deferasirox are oral iron chelators approved by the FDA for treatment of patients with thalassemia who have iron overload.

**Therapy With Parenteral Iron**

When oral iron therapy fails, parenteral iron administration may be an effective alternative. Common indications are iron malabsorption (e.g., sprue, short-bowel syndrome), severe oral iron intolerance, as a routine supplement to total parenteral nutrition, and in patients who are receiving erythropoietin. Parenteral iron can be given to iron-deficient patients and pregnant women to create iron stores, something that would take months to achieve by the oral route. The indications for parenteral iron therapy include documented iron deficiency and intolerance or irresponsiveness to oral iron.

The rate of hemoglobin response is determined by the balance between the severity of the anemia (the level of erythropoietin stimulus) and the delivery of iron to the marrow from iron absorption and iron stores. When a large intravenous dose of iron dextran is given to a severely anemic patient, the hematologic response can exceed that seen with oral iron for 1–3 weeks. Subsequently, however, the response is no better than that seen with oral iron.

Parenteral iron therapy should be used only when clearly indicated because acute hypersensitivity; including anaphylactic and anaphylactoid reactions, can occur. Other reactions to intravenous iron include headache, malaise, fever, generalized lymphadenopathy, arthralgias, urticaria, and, in some patients with rheumatoid arthritis, exacerbation of the disease.

Several iron formulations are available in the U.S. (Larson and Coyne, 2014). These include iron dextran, sodium ferric gluconate, ferumoxytol, iron sucrose, and ferric carboxymaltose. Ferumoxytol is a semisynthetic carbohydrate-coated superparamagnetic iron oxide nanoparticle approved for treatment of iron deficiency anemia in patients with chronic kidney disease; the ferumoxytol has to be administered safely as a 1.02-g infusion. Given intravenously in a dose less than 500 mg, the iron dextran complex is cleared with a t1/2 of 6 h. When 1 g or more is administered intravenously as total-dose therapy, reticuloendothelial cell clearance is constant at 10–20 mg/h.

Intramuscular injection of iron dextran should be initiated only after a test dose of 0.5 mL (25 mg of iron). If no adverse reactions are observed, the injections can proceed. The daily dose ordinarily should not exceed 0.5 mL (25 mg of iron) for infants weighing less than 4.5 kg, 1 mL (50 mg of iron) for children weighing less than 9 kg, and 2 mL (100 mg of iron) for other patients. However, local reactions and the concern about malignant change at the site of injection make intramuscular administration inappropriate except when the intravenous route is inaccessible. The patient should be observed for signs of immediate anaphylaxis and for an hour after injection for any signs of vascular instability or hypersensitivity, including respiratory distress, hypotension, tachycardia, or back or chest pain. Delayed hypersensitivity reactions also are observed, especially in patients with rheumatoid arthritis or a history of allergies. Fever, malaise, lymphadenopathy, arthralgias, and urticaria can develop days or weeks following injection and last for prolonged periods of time. Use iron dextran with extreme caution in patients with rheumatoid arthritis or other connective tissue diseases and during the acute phase of an inflammatory illness. Once hypersensitivity is documented, iron dextran therapy must be abandoned.

With multiple total-dose infusions such as those sometimes used in the treatment of chronic GI blood loss, accumulations of slowly metabolized iron dextran stores in reticuloendothelial cells can be impressive. The plasma ferritin level also can rise to levels associated with iron overload. It seems prudent, however, to withhold the drug whenever the plasma ferritin rises above 800 μg/L.

**Sodium Ferric Gluconate.** Sodium ferric gluconate is an intravenous iron preparation with a molecular size of about 295 kDa and an osmolality of 990 mOsm/kg. Administration of ferric gluconate at doses ranging from 62.5 to 125 mg during hemodialysis is associated with transferrin saturation exceeding 100%. Unlike iron dextran, which requires processing by macrophages that may require several weeks, about 80% of sodium ferric gluconate is delivered to transferrin within 24 h. Sodium ferric gluconate also has a lower risk of inducing serious anaphylactic reactions than iron dextran (Sengolge et al., 2005).

**Iron Sucrose.** Iron sucrose is a complex of polymeric iron (III) hydroxide in sucrose (Beguin and Jaspers, 2014). Following intravenous injection, the complex is taken up by the reticuloendothelial system, where it dissociates into iron and sucrose. Iron sucrose appears to be better tolerated and to cause fewer adverse events than iron dextran (Hayat, 2008). This agent is FDA-approved for the treatment of iron deficiency in patients with chronic kidney disease. Chronic use has the potential to cause renal tubulointerstitial damage (Agarwal, 2006).

**Ferric Carboxymaltose.** Ferric carboxymaltose is an iron complex consisting of a ferric hydroxide core and a carbohydrate shell (Keating, 2015). With this preparation, a replenishment dose of up to 1000 mg of iron can be administered in 15 min. Intravenous administration results in transient elevations in serum iron, serum ferritin, and transferrin saturation, with subsequent correction in hemoglobin levels and replenishment of depleted iron stores. Ferric carboxymaltose is rapidly cleared from the circulation, becoming distributed (~80%) in the marrow, as well as the liver and spleen. Common reported drug-related adverse effects include headache, dizziness, nausea, abdominal pain, constipation, diarrhea, rash, and injection site reactions. However, the incidence of drug-related adverse events appears similar to those of patients treated with oral ferrous sulfate.
Ferric carboxymaltose is FDA-approved for therapy of iron deficiency anemia.

**Copper, Pyridoxine, and Riboflavin**

Copper

Copper has redox properties similar to those of iron, which simultaneously are essential and potentially toxic to the cell. Cells have virtually no free copper. Instead, copper is stored by metallothioneins and distributed by specialized chaperones to sites that make use of its redox properties. Transfer of copper to nascent cuproenzymes is performed by individual or collective activities of P-type ATPases, ATP7A and ATP7B, which are expressed in all tissues (Nevitt et al., 2012). In mammals, the liver is the organ most responsible for the storage, distribution, and excretion of copper. Mutations in ATP7A or ATP7B that interfere with this function have been found responsible for Wilson disease or Menkes syndrome (steely hair syndrome) (de Bie et al., 2007), respectively, which can result in life-threatening hepatic failure.

Copper deficiency is extremely rare; the amount present in food is more than adequate to provide the needed body complement of slightly more than 100 mg. Even in clinical states associated with hypoproliferation (sprue, celiac disease, and nephrotic syndrome), effects of copper deficiency usually are not demonstrable. Anemia due to copper deficiency has been described in individuals who have undergone intestinal bypass surgery, in those who are receiving parenteral nutrition, in malnourished infants, and in patients ingesting excessive amounts of zinc (Willis et al., 2005). Copper deficiency interferes with the absorption of iron and its release from reticuloendothelial cells. In humans, the prominent findings have been leukopenia, particularly granulocytopenia, and anemia. Concentrations of iron in plasma are variable, and the anemia is not always microcytic. When a low plasma copper concentration is determined in the presence of leukopenia and anemia, a therapeutic trial with copper is appropriate. Daily doses up to 0.1 mg/kg of cupric sulfate have been given by mouth, or 1–2 mg per day may be added to the solution of nutrients appropriate. Daily doses up to 0.1 mg/kg of cupric sulfate have been given by mouth, or 1–2 mg per day may be added to the solution of nutrients for parenteral administration.

**Pyridoxine**

Patients with either hereditary or acquired sideroblastic anemia characteristicly have impaired hemoglobin synthesis and accumulate iron in the perinuclear mitochondria of erythroid precursor cells, so-called ringed sideroblasts. Hereditary sideroblastic anemia is an X-linked recessive trait with variable penetrance and expression that results from mutations in the perinuclear mitochondria of erythroid precursor cells, so-called ringed sideroblasts. Hereditary sideroblastic anemia is an X-linked recessive trait with variable penetrance and expression that results from mutations in the erythrocyte form of δ-aminolevulinate synthase.

Riboflavin

The spontaneous appearance in humans of red cell aplasia due to riboflavin deficiency undoubtedly is rare, if it occurs at all. Riboflavin deficiency has been described in combination with infection and protein deficiency, both of which are capable of producing hypoproliferative anemia. However, it seems reasonable to include riboflavin in the nutritional management of patients with gross, generalized malnutrition.

**Vitamin B12, Folic Acid, and the Treatment of Megaloblastic Anemias**

Vitamin B12 and folic acid are dietary essentials. A deficiency of either vitamin impairs DNA synthesis in any cell in which chromosomal replication and division are taking place. Because tissues with the greatest rate of cell turnover show the most dramatic changes, the hematopoietic system is especially sensitive to deficiencies of these vitamins.

**Cellular Roles of Vitamin B12 and Folic Acid**

The major roles of vitamin B12 and folic acid in intracellular metabolism are summarized in Figure 41–4. Intracellular vitamin B12 is maintained as two active coenzymes: methylcobalamin and deoxyadenosylcobalamin.

Methylcobalamin (CH3-B12) supports the methionine synthetase reaction, which is essential for normal metabolism of folate (Weissbach, 2008). Methyl groups contributed by methyltetrahydrofolate (CH3-H4PteGlu) are used to form methylcobalamin, which then acts as a methyl group donor for the conversion of homocysteine to methionine. This folate-cobalamin interaction is pivotal for normal metabolism of DNA. The methionine synthetase reaction is largely responsible for the control of the recycling of folate cofactors; the maintenance of intracellular concentrations of polyglutamates; and, through the synthesis of methionine and its product SAM, the maintenance of a number of methylation reactions.

Deoxyadenosylcobalamin (deoxyadenosyl B12) is a cofactor for the mitochondrial mutase enzyme that catalyzes the isomerization of l-methylmalonyl CoA to succinyl CoA, an important reaction in cellular metabolism.

**History**

The discovery of vitamin B12 and folic acid is a dramatic story that began almost 200 years ago and includes two Nobel Prize–winning discoveries. Beginning in 1824, Combe and Addison wrote a series of case reports describing what must have been megaloblastic anemias (still known as Addisonian pernicious anemia). Austin Flint in 1860 first described a severe gastric atrophy and called attention to its possible relationship to the anemia. After Whipple’s observation in 1925 that liver is a source of a potent hematopoietic substance for iron-deficient dogs, Minot and Murphy carried out Nobel Prize–winning experiments that demonstrated the effectiveness of the feeding of liver to reverse pernicious anemia. Soon thereafter, Castle defined the need for both intrinsic factor, a substance secreted by the parietal cells of the gastric mucosa, and extrinsic factor, the vitamin-like material provided by crude liver extracts. Nearly 20 years passed before Riches and coworkers and Smith and Parker isolated and crystallized vitamin B12; Dorothy Hodgkin received the Nobel Prize for determining its X-ray crystal structure.

As attempts were being made to purify extrinsic factor, Wills and her associates described a macrocytic anemia in women in India that responded to a factor present in crude liver extracts but not in the purified fractions known to be effective in pernicious anemia. Soon thereafter, Castle defined the need for both intrinsic factor, a substance secreted by the parietal cells of the gastric mucosa, and extrinsic factor, the vitamin-like material provided by crude liver extracts. Nearly 20 years passed before Riches and coworkers and Smith and Parker isolated and crystallized vitamin B12; Dorothy Hodgkin received the Nobel Prize for determining its X-ray crystal structure.
